[61145.]—**Does it Boil?**—I venture to think that the idea of the steam "displacing" the atmosphere is proving a stumbling-block to "Weald." I take it that the steam only displaces the air in something the same sort of way that claret in a tumbler is displaced by letting water run into it from a tap. The wine and water mixing, both run over together, and the proportion of wine constantly diminishes till it practically disappears. This is quite a different process from the displacement of the water in a pump cylinder by the intrusion of the plunger. "Weald" must realise that two gases in communication with each other mix completely, whatever their relative pressures and densities may be, so that the displacement of one by the other is a question of quantity rather than of pressure. It requires a wonderful deal of thinking to get any clear ideas into one's head concerning such impalpable bodies as gases. I find it a great help in trying to realise unfamiliar aspects of familiar things to learn about the corresponding phenomena of a less homely nature. In this case other gases behave in analogous ways, and the demonstration of the fact is a marvellous triumph of experimental physics, and the study of it throws great light on our every-day kettle-boiling, if we will be at the pains to consider it. Yes, it seems that nature does forbid water and other liquids to be heated beyond certain points, varying with the pressure, without passing at once into vapour, for every particle of water that attains that temperature at once flashes into steam if it be in an open vessel. If the vessel be closed, temperature and pressure rise together. It will not do to regard the atmosphere above a pan of heated water as acting like a lid that has to be lifted to allow the steam to escape. Neither does it do to rely on "solvent action" as an explanation of vaporisation. Recurring to books, I think that one reason why people often find them unhelpful is that when for any reason they fail to get the meaning out of the words they cannot question the author and get him to use other words. I find that in such cases reading another book differently expressed often clears away the mist. The objection itself is as old as Socrates.—W. A. S. B.

[61145.]—**Does it Boil?**—With reference to this query the following extract may be of interest. "Among the many extraordinary natural phenomena attending the recent eruption of Mount Tarawera, one which appears to me not the least singular, says a correspondent of the *New Zealand Herald*, has been passed over in comparative silence, and without exciting comment among the scientific or unscientific public. During the last week those attending Mr. Burton's interesting lectures have heard there related one of the strange and so far inexplicable circumstances witnessed by Mr. McRae and others of that devoted little band, to whom it must have seemed that hell itself had opened to destroy them—I allude to the fact of their being unable to make water boil on that terrible night, when earth itself appeared to be in a state of ebullition. Mr. McRae says:—'I made George Baker, the cook, put some water on the fire to make cocoa for the women, who were cold and shivering, poor souls, though holding up grandly. About three-quarters of an hour afterwards he met me in the passage and said to me 'Come here, sir.' 'What is it?' said I. 'I can't get the water to boil,' he said. 'Tut,' said I, 'poke up the fire.' 'It's a good fire,' he replied; and so it was, a glowing fire of blazing rata logs—a splendid fire. 'Put your hand in there and feel it,' said he, taking the lid off the boiler. I did so—very gingerly, I assure you—and found the water as cold as when he put it on. There were so many extraordinary things happening around me that this particular one did not excite my wonder very much. I thought it was owing to the electricity in the air. George Baker can vouch, as well as myself, for the fact of the water having been on the fire for three-quarters of an hour, and at the end of that time being as cold as when it was put on. We spoke of the circumstance to the others at the time as being curious, but soon had matters more serious to distract our attention." Now, surely, here is a natural phenomenon worthy the investigation of all our scientific men, not only in New Zealand, but throughout the civilised world. We, of course, all know that the greater the atmospheric pressure the greater the number of units of heat required to make the water boil; but some other deterrent cause must have been at work in this instance, as after having been placed for three-quarters of an hour on a good fire the water remained absolutely cold. What other cause was there? is the problem I suggest to our scientific men as one well worthy of their research. —ALEX FRASER.

[61150.]—**Hydraulic or other Press.**—Any maker of hydraulic presses will supply what you want. See their catalogues.—E. G. M.

[61153.]—**Blowing Fan.**—The density of a fan blast is usually given in "ounces per inch." Divide the velocity of the fan tips in feet per second by 4; square the result, and then divide by the product of the diameter of fan in feet by 120. The pressure in pounds per square inch is usually found by squaring the velocity of the fan tips in feet per second and dividing by 97,300. To find the cubic feet delivered per minute write—

$$C = \frac{v\,a\,k}{2{\cdot}6},$$

where a = area of outlet in sq. in., v velocity in ft. through a, and k a co-efficient varying slightly with temperature, 1·01 for 37°, 1·1 for 82°.—H. N.

[61152.]—**Spanish.**—The grammar you have is a good one; but for learning a language quickly there is nothing like the Hamiltonian system, as it is termed—that is, interlined translation. I mean, of course, for those who want to learn—not for schoolboys.—TUTOR.

[61155.]—**The Pantanemone.**—I have not seen any reply to this query yet, although it refers to a windmill which, if I recollect, several of your readers were going to make. The only reports of its performance were in model form; but now that we have a discussion on horizontal windmills it may be interesting to ask what about the Pantanemone. I am inclined to think the "horizontal" will beat it for work done and durability, although as the pantanemone might have steel wire for strengthening, it would be much lighter. That seems its chief recommendation. See Nos. 504, 510, and 511 for some suggestions.—SAML. RAY.

[61190.]—**Differential Feed.**—While thanking "T. C., Bristol," for his reply to this query, I beg to say that I inadvertently omitted to state that screw was left-handed. How does this alter the case, and what wheels would cut 3 threads and 4 threads per inch, and a pitch ·148in. respectively, with a screw 4 threads per inch? What alteration does the introduction of 1, 2, or more intermediate wheels make: must there be always an even number of intermediate wheels? I would feel obliged to "T. C.," or any other of our able correspondents, for information on the above; and no doubt it will be interesting to a large number of our engineering friends to see the question of differential feeds clearly demonstrated.—A BELATED FOREMAN.

[61234.]—**Bursting Pressure.**—I can hardly think that the evident error of 14476 × 2 = 28952 which is given as 22952 can be the error to which you draw attention; but I can see no other, as the movement is in proportion of 14476 to 1. Kindly say where you believe I am wrong.—T. C., Bristol.

[61233.]—**Permanent Way.**—"Holland" is not quite correct in stating that the only rails in use on the Continent are flat-bottomed. Last September I travelled over the Western of France, from Havre, via Paris, to St. Malo, altogether about 450

FIG. 1.

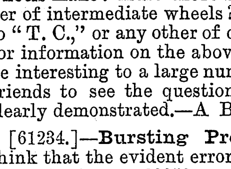

FIG. 2.

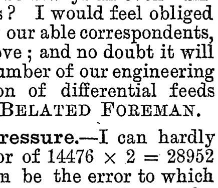

FIG. 3

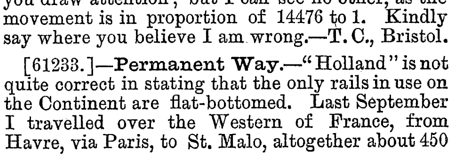

miles. Throughout this length I did not notice a single length of flat-bottomed rails, except on some single branch lines and state lines. The double-headed rails and chairs have evidently been in use some time, and are short and light except in newly-laid places. The sketches below show the method of laying and fishing rails on several leading

FIG. 4

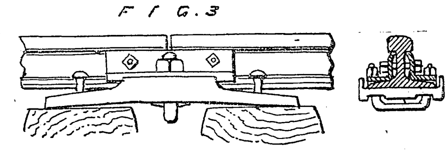

FIG 5

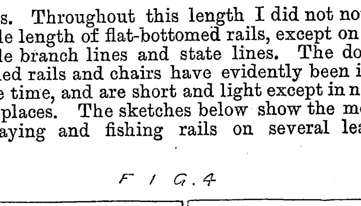
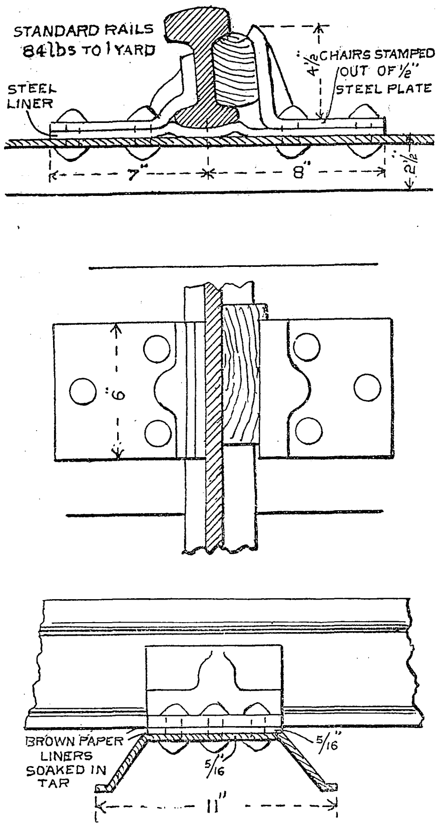


American lines. Fig. 1, Leigh Valley Ry., 66lb. per yard; Fig. 2, Pennsylvania Ry., 60lb. per yard; Fig. 3, the "Fisher" rail joint in use in America; Fig. 4, West Shore Railway method of joining rails (N.B.—The joint of one rail s laid opposite the centre of the other. Number of sleepers, 2180 to one mile of single rail); Fig. 5, standard rail 67lb. per yard. There is, I believe, much difference of opinion

over there as to whether suspended or supported joints are best. The supported joints were adopted in making the West Shore line, which is the first trunk line in America which has been built from

FIG. 6



the outset as a double line, with easy gradients and few sharp curves. The same joints have now been adopted on the New York Central. I also inclose a diagram of Webb's steel road, as in use on the L. and N.W.R. (Fig. 6).—NO NAME.

[61274.]—**Portable Battery.**—A very good battery for ordinary testing purposes is the Insulite. The smallest size goes into the pocket easily, and there is no chance of spilling the liquid. Besides, one advantage is that the resistance is much less than that of a so-called dry battery. I use one having a cork tightly squeezed into the charging hole, and then made a small hole—sufficient to let gas escape, but too small for the liquid to spill—in the centre of it with a red-hot wire. With a horizontal Trouvé detector, it works well, giving 5° deflection through 10,000w. Insulation tests are easily taken with this portable apparatus. If galvanometer is shunted it reads from ·05 ampère to 2 ampères. A month or two ago there was an article on "A Dry Battery," by a Mr. Roberts in the *Electrical Engineer*, but since then I have heard nothing of it. Does anyone know what it is or where it is to be had? It has a total capacity of 20 ampère hours, so it might suit the needs of this querist?—IOTA.

[61274.]—**Portable Cell.** —"Ohm" ought to know better than to recommend anybody such an antiquated and clumsy affair—a thing that would begin to "creep" before it had been three days in use, and would drive its possessor wild through every now and then drying up and giving no deflection at all, and would bewilder any experimenter by the eccentric results it would give frequently by total or partial evaporation. If anybody wants a portable cell for testing, let him take the following: Make a small rectangular box (1½in. by 2in. is a convenient size), get a small Leclanché or other carbon (arc-lamp carbons will do) with either a leaden head and terminal, or a brass clamp, and strap to the face or faces of it one or more "agglomerates" (hard blocks of peroxide of manganese, which are made in all sizes) by a couple of elastic bands. Line the box with sheet zinc, having the necessary terminal; amalgamate the zinc well, and then place the carbon, with its agglomerates, in the middle, and pack it round carefully with the following mixture: Powdered sal-ammoniac two-thirds; plaster of Paris one-third, or a little less by bulk. Spoon the mixture in small quantities into the cell, drop a little water in, and mix it up thoroughly with a piece of stiff wire, putting some of it under the bottom of the carbon, so that it touches nothing but the mixture, which swells rapidly, and sets in a few minutes, and you have a thoroughly good testing cell, which will last for many months, if well made, and of E.M.F. 1·42. The action, on closing the circuit, is (1) an electric current caused by (2) sal-ammoniac attacking zinc; H liberated, which combines with the O of the MnO_2 (agglomerate) to form H_2O—i.e., water, which thus keeps the cell wet enough to work without anything running out, and the mixture, being porous, allows of the free escape of the gas, that proves so troublesome in hermetically sealed cells (e.g., Clarke's chloride of silver and others), while there is no loose liquid to run out, the water being generated in exact proportion to the electrical action—i.e., to the need for it. The whole affair may be only the size of a pepperpot. Cast zinc cases, if procurable, are still better, and save all trouble of making a case; but the zinc must be cast, not soldered. They are also very cheap in cost.—EDWARD CONRY.

[61293.]—**Compound Loco. on Cal. Ry.**—"Rover" is entirely misinformed as regards above engine. It is not a compound engine; it has the Bryce-Douglas valve motion, which is just light enough for the work it has to perform—hence the breakdown. The fault lies with the Cal. Ry., not with the builders, who turned out a first-class job, according to drawings supplied by Mr. Drummond. —ONE WHO KNOWS.

[61295.]—**Turning Slate.**—Yes, carbonado is dear; but everlasting, so to speak. It will cut anything, and does not seem to wear.—R. S. T.

[61299.]—**Capricious Dynamo.**—The statement made by "Selim" leads one to think that "Miller" was right in his conjecture as to the probable cause of the defect in his dynamo. If the series coils had been of such small proportions that the machine would have worked satisfactorily without them, the polarity would not have been reversed. Evidently the fields are wound with too large a proportion of series wire. In case the polarity is again reversed, "Selim" might try rewinding the field magnets as a shunt, and discarding the series coils altogether. Very probably the gauge of wire at present in use for the shunt coils would not answer very well, as the additional wire would increase the resistance to such an extent (in comparison with that of the external circuit) as to prevent the fields from being properly magnetised. If "Selim" measures the res. of the present shunt coils, and uses a thicker wire in the new ones, so that their resistance about equals that of the present coils, he can't be far wrong.—J. H. H.

[61302.]—**Billiard Tables.**—The difference in championship tables is that pocket openings should not exceed 3in. in the most narrow part. The championship table does not otherwise differ, except in size of pocket openings, from usual. The ordinary table varies from $3\frac{5}{16}$in. to 3½in. in pockets. Tables for private use should be slightly smaller than if intended for public use (in the pockets). Size of slate bed top (this is the measurement always taken) 12ft. by 6ft. 1½in. equalling 11ft. 8in. by 5ft. 9½in. from point to point of cushion.—J. ASHCROFT, Liverpool.

[61310.]—**Electricity for Killing Dogs.**—A man is better than a dog or a cow; but that is no reason why, if for man's benefit, the dog or cow has to be killed, it should not be done in the least painful way consistent in the case of a bullock with the flesh being good to eat. Let W. J. Grey use his pen to assist men and women, and he will find plenty to follow suit.—R. S. T.

[61319.]—**Photographic.**—TO "BOBADIL" AND G. EDWINSON.—The gold terchloride should be rendered perfectly neutral by driving off all excess acid. This should be done at a lower temperature than that employed in an earlier part of the evaporating process. When the acid solution has been evaporated down to a dark red thick liquid, it should be frequently made to flow around the sides of the capsule, and allowed to dry there, forming a mass of dark red crystals. Free acid left in the solution will cause a loss of gold and cyanide. Watts is right in advising a correction with a few more drops of terchloride solution.—GEORGE EDWINSON.

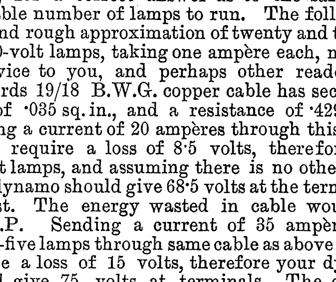
[61324.]—**Hardening and Tempering Small Saws.**—Saws for cutting the slots in screw-heads are often made of a steel that does not require hardening or tempering, the warping being consequently avoided. You had better use the same kind.—A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61327.]—**Potentiometer.**—TO "SIGMA."—For accurate results (accurate, of course, subject to the definition of what value of volt is used) the standard cell and the battery producing a current are both necessary; but for approximate measures the plan referred to will answer well enough; its uncertainty is due to the fact that the E.M.F. of the Daniell cell is variable, and that unless the resistances are large, the experiment itself tends to disturb the E.M.F. I have frequently used a plan closely resembling the one proposed: Take 1, 2, or 3 cells, according to degree of force to be measured, and close their circuit through a total resistance, including that of the cells, a thousand times as great in ohms as the acting E.M.F. in volts, so that a current of one-thousandth of an ampère passes. In these conditions we can take any part of the resistance which is divided out, and if we connect to the two ends the wires from the E.M.F. to be measured, be it a cell or part of a circuit, with a large resistance and a delicate galvanometer, shifting one connection along the resistance until the galvanometer shows no current, we have two equal E.M.F.'s opposed (of course making the connections so as to oppose them). Now the ohms of the interposed resistance will be the measure of the E.M.F. (or a thousand fold) which is employed in driving current through that resistance; thus another Daniell would take a space of 1,075 ohms interposed to show no current. —SIGMA.

[61330.]—**Legal.—Bad Dry Plates.**—I can sympathise with J. W. Elphee in the matter of bad plates, and so can all photographers who do not use quantity enough to entitle them to buy direct from the makers. Most dealers will exchange a box of plates, if it is unbroken; but I do not think they could be compelled to do so in a court of law without a great deal of trouble. For instance, you complain of loss of sensitiveness. In whose hands can you localise this loss; was it in the makers, or the carriers, or the dealers, or your own? Again, what is the standard of sensitiveness, and does the maker, or dealer, profess to sell them as possessing this or any other standard.—B. SC. (and Solicitor), Plymouth.

[61331.]—**Electric Light.**—Providing they are not of such very low resistance as to absorb a large current, and that your dynamo will give you a little higher E.M.F., you can certainly run more than twenty 20c.p. lamps on a 19/18 B.W.G. copper cable. I should say you could safely run up to 30 or 35 lamps. You should have given the E.M.F. of the dynamo, and E.M.F. and C. required by the lamps, for a correct answer as to the safe and advisable number of lamps to run. The following safe and rough approximation of twenty and thirty-five 60-volt lamps, taking one ampère each, may be of service to you, and perhaps other readers:—600 yards 19/18 B.W.G. copper cable has sectional area of ·035 sq. in., and a resistance of ·429 ohm. Sending a current of 20 ampères through this cable would require a loss of 8·5 volts, therefore for 60-volt lamps, and assuming there is no other lead, your dynamo should give 68·5 volts at the terminals, at least. The energy wasted in cable would be ·215H.P. Sending a current of 35 ampères for thirty-five lamps through same cable as above would require a loss of 15 volts, therefore your dynamo should give 75 volts at terminals. The energy wasted in cable would be ·7 H.P. If you use higher resistance lamps, the conditions will, of course, be more favourable. You can, I think, from the two approximations choose the number of lamps you would wish to increase to. I have tried to make it as plain as possible under pressure, and shall be pleased to give you any further information you may wish. The breakage of filaments was, no doubt, from fault in carbon or jointing, or over running.—LANCASTER.

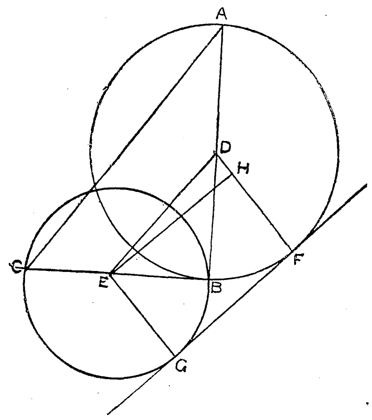
[61336.]—**Geometrical.**—Let A D C, B E C be semicircles described on A C, B C, the side of a right-angled triangle; O, P, their centres, D, E the points of contact of the common tangent D E. Join O D, P E, and O P, and draw P F parallel to D E. Then F P is equal to D E, and F D to P E; therefore, F D is equal to P C, and since O D is equal to O C, O F is equal to O C − C P. Now, in the right-angled triangle O F P,



$$F P^2 = O P^2 - O F^2;\ \text{but}\ O P^2 = OC^2 + C P^2;$$
$$\text{and}\ O F^2 = (O C - C P)^2 = O C^2 + C P^2 - 2 O C . C P.$$
$$\therefore F P^2 = 2 O C . C P;$$
$$\text{or}\ D E^2 = \frac{A C . C B}{2}.$$
$$= \text{area triangle } A B C.$$—MILVERTON.

[61336.]—**Geometrical.**—Let A B C be the given right-angled triangle, and D and E the cen-

tres of the circles described on A B, B C, the sides containing the right angle. Let G F be the common tangent to these two circles, and draw

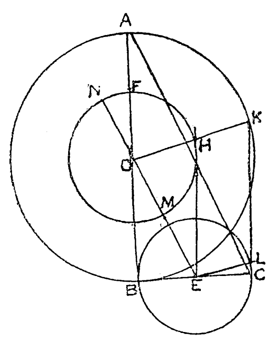


E G, D F, and E H parallel to G F. Let D F = R, and E G = r. Then we have—

$$D E^2 = R^2 + r^2,$$
$$\text{and } D E^2 = D H^2 + H E^2 = (R - r)^2 + G F^2$$
$$\therefore R^2 + r^2 = (R - r)^2 + G F^2;$$
$$\text{or, } R^2 + r^2 = R^2 + r^2 - 2 Rr + G F^2;$$
$$\therefore G F^2 = 2 Rr.$$

Now, 2 Rr is evidently the area of the triangle A B C. Hence the square on G F is equal in area to the triangle A B C.—J. E. GORE.

[61336.]—**Geometrical.**—Let A B C be a right-angled triangle, B being the right angle. Let circles be described on A B and B C as diameters. The square on the common tangent to these circles is equal to the triangle A B C. Bisect A B and B C in D and E. Make A G = B E or E C. With D as centre and D E as radius, describe a circle, and from E draw a tangent meeting it in H. Produce the line D H to meet the circle on A B in K. Draw E L parallel to D K to meet the circle



on B C in L. Join K L. K L is a tangent to the circles on A B and B C. Join H E. H K is equal and parallel to E L, K L is equal and parallel to H E, and the angles at L and K are right angles. ∴ K L is a tangent to both circles. Join D E, and let it cut the circle N G H M in N and M. Then, since H E touches the circle N G H M, H E² or K L² = N E. E M = (D E + D N) (D E − D N) = (D E² − D N²) = (D B² + B E²) − (D B − B E)² = 2 D B. B E = A B × $\frac{B C}{2}$ = area of triangle A B C.—*Q. E. D.*—J. C. KELLY.

[61341.]—**Colouring on Parchment.**—This is one of the most trying and difficult jobs an architect or surveyor has to contend with, and requires considerable practice before a large surface of parchment can be coloured a nice even and level tint. The colours should not be dark, and Prussian blue avoided altogether, as it dries too quickly and in patches. After inking in the plan, start colouring at the top, with your parchment on an inclined plane; use a medium-sized brush and fairly well filled with colour, so that the lower edges will not get dry before you can follow on; get over the work as quickly as possible, always taking care not to get the brush dry; keep a piece of blotting paper under your hand ready to empty the brush when getting close to the bottom of your work, and finish off with a half-dry brush round the bottom lines. No damp should be applied to the skin before colouring, neither should it be too dry. The least drop of liquid ox-gall (see Sale Column last week) mixed with the colour makes it flow better and more evenly over the greasy parts of the parchment. Further instructions are given for colouring on parchment, ivory, &c., with the above ox-gall.—ARCHITECTUS.

[61345.]—**Pneumatics.**—There is an important omission in this query. The sectional area of the large gasholder at water level should have been given; also the contents of the small holder are too small, as it will be found that if the sectional area of the larger holder is more than 23 sq. ft., the problem is impossible to solve. If a volume of gas, represented by V cubic feet at the pressure of the atmosphere, is compressed into a space of C cubic feet, we get by "Boyle's Law" the proportion—

$$V : C :: 15 + P : 15$$

P being pressure per square inch on the interior of the close vessel, and 15lb. being the atmospheric pressure, from which we get $V = \frac{C\,(15 + P)}{15}$. The contents of the large holder are 200 cub. ft., call this C; the pressure 5lb., call this P; the pressure in the small holder 5¼lb., call this p; when the two are connected, the pressure will be 5¼lb., or p in both, under the circumstances stated in the query, and we require to know how many cubic feet must pass from the small to the large holder in order to produce this equilibrium. Call this quantity n cub. ft. at pressure p. Now, if this n cub. ft. were allowed to expand to atmospheric pressure, and also the C cub. ft. to expand to the same pressure, and the two added together, the volume (call it V′) would be from the equation given above—

$$\frac{n\,(15 + p)}{15} + \frac{C\,(15 + P)}{15} = V'.$$

Now, suppose the water in which the large holder floats to become solid (as it well might in this weather!), then suppose V′ to be compressed into the space C above the water in the large holder, we get

$$V' : C :: 15 + p : 15,$$

V′ having taken the place of V, and p that of P. Restore the value of V′, and form an equation, and after reduction it will be found that $n = \frac{C\,(p - P)}{15 + p}$, which represents the number of cub. ft. of gas at pressure p, which have passed from the small to the large holder to produce a pressure p in both. Now suppose the water to become liquid, the extra pressure of p − P, or ¼lb., will force the water down; and as every lb. of pressure on the square inch would force it down about 2ft., the extra pressure of (p − P) lb. would force it down 2 (p − P) feet. This, multiplied by the area A, will give 2 A (p − P) cub. ft. as the additional space in the holder caused by the extra pressure. As this space is to be filled with gas at pressure p of the small holder, we get 2 A (p − P) cub. ft. of gas at pressure p, which passes from the small to the large holder, and this must be added to the value of n found above, so that the total cub. ft. which pass from one holder to the other is represented by

$$(p - P)\left\{\frac{C}{15 + p} + 2\,A\right\}$$

Not having been given the value of A, I cannot work this out numerically; but it will be found that if A is made equal to 23 sq. ft., there will be no gas left in the small holder.—M.I.C.E., Bath.

[61346.] — **Cementing Lenses.** — Canada balsam has always a yellowish tint. Dilute with chloroform if it is too thick. You will require some practice before you can cement a 3in. lens without air-bubbles.—B.SC., Plymouth.

[61348.]—**Length of Chord.**—The following will give the chord (where arc and radius are given), approximately without using mathematical tables:—

$$\frac{c}{2} = \sqrt{(2\,R - V)\,(V)}$$

$$\frac{c}{2} = \sqrt{2\,R\,V - V^2}$$

$$\frac{c}{2} = \sqrt{2\,R\,\frac{0{\cdot}13\,L^2}{R} - \left(\frac{0{\cdot}13\,L^2}{R}\right)^2}$$

When c = chord, R = radius, L = length of arc, and V = versed sine.—DUD. DUDLEY.

[61348.]—**Length of Chord.**—ERRATUM.—By some unhappy chance, in the answer given to this question on p. 439 the coefficient of the series has been omitted. The answer should be:—If D be the diameter of the circle, and A the length of the given arc, then the length of the chord

$$= A\left\{1 - {\cdot}1666\left(\frac{A}{D}\right)^2 + {\cdot}00833\left(\frac{A}{D}\right)^4 - {\cdot}0002\left(\frac{A}{D}\right)^6 + \&c.\right\}$$

To use this formula, A should not be much greater than D; if A is not greater than D, three terms might be sufficiently exact in ordinary cases.—MILVERTON.

[61352.] — **Lantern Exhibition.** — I should think three hours too long for an exhibition; from one and a half to two should suffice. Five to six dozen slides would give a good entertainment. I have one slide that would take twenty minutes itself to describe; others that would take from one to five minutes. As to what subjects are most suitable, you should be best able to answer that yourself: much depends on your own taste, aim, and object in exhibiting, also audience—adult or junior. "Many men many minds." If you wish to enforce temperance principles choose temperance subjects; if religious, Bible subjects, "Pilgrim's Progress," &c.; and so on. Any slide maker will send you a list, in which you will find subjects to suit all tastes. I cannot give definite information about "litho. lantern pictures." I thought these were supplied ready made only. You can purchase chromo transfer pictures and put them on glass yourself (full instructions accompany sheets). They do not make very good slides; but being coloured please children very well. I have a number of them which I exhibit with an oil lantern. I do not think they would answer so well with limelight, as the defects would be too well seen. Further advice, if desire, by writing to—R. BARCLAY, Gariochsford, Forgue, Huntly.

[61353.]—**Spirals.**—If the equation of any spiral showing the nature of the curve and the co-ordinates of its extremity be given, then its length, as compared with a straight line, can be found either exactly or approximately. If the equation be given in polar co-ordinates, the length of the curve $= \int (d\,r^2 + r^2\,d\,\theta^2)^{\frac{1}{2}}$. For example, take the spiral of Archimedes, which is a curve in which the radius vector varies directly as the vectorial angle. Its equation is $r = \frac{a}{2\,\pi}.\theta$, in which a is the value of the radius vector. When starting from the origin it has made one complete revolution. From the given equation we have—

$$d\,r = \frac{a}{2\,\pi}.d\,\theta$$

$$\therefore d\,r^2 + r^2\,d\,\theta^2 = \frac{a^2}{4\,\pi^2}(1 + \theta^2)\,d\,\theta^2$$

$$\therefore S = \frac{a}{2\,\pi}\int (1 + \theta^2)^{\frac{1}{2}} d\theta$$

$$\text{But } \int (1 + \theta^2)^{\frac{1}{2}}\,d\,\theta = \frac{\theta}{2}\,(1 + \theta^2)^{\frac{1}{2}} + \tfrac{1}{2}\log._{\varepsilon}(\theta + \sqrt{1 + \theta^2})$$

∴ the length of the spiral from the origin for any value of θ—

$$= \frac{a}{4\,\pi}\,[\theta\sqrt{1 + \theta^2} + \log._{\varepsilon}(\theta + \sqrt{1 + \theta^2})]$$

As a numerical illustration, suppose it is required to find the length of the first whorl of this spiral.

$$\text{Then } \theta = 2\,\pi = 6{\cdot}2832,\ \sqrt{1 + \theta^2} = 6{\cdot}363$$
$$\theta + \sqrt{1 + \theta^2} = 12{\cdot}6462$$
$$\log._{\varepsilon}\,\theta + \sqrt{1 + \theta^2} = \log._{\varepsilon}\,12{\cdot}6462 = 2{\cdot}5373$$
$$\therefore \text{length of first whorl} = a\,(3{\cdot}1865 + {\cdot}202) = a \times 3{\cdot}3885$$

—MILVERTON.

[61354.] — **Photographs** (1) Turn yellow after mounting, through want of thorough elimination of the hypo. Another cause is the use of an old mountant: the paste should be fresh made on the day it is used. (2) Moonlight photos can be taken with any make of plates; of course, the more rapid they are, the less time is lost.—B.SC., Plymouth.

[61358.] — **Dead Point — Legal.**—Supposing "Another Workman" were as stupid as the person who signs himself "Not a Workman," and followed his ridiculous, not to say wicked, advice, and the naturally-to-be-expected smash resulted, would "Not a Workman" be liable for damages, manslaughter, &c.? Truly the place "where the piston stopped" might be the "dead point"—of "Another Workman"—but certainly not (except by the merest chance) of any ordinary horizontal engine.—J. BROWN, Belfast.

[61360.]—**Revolving Apparatus.**—I opine you will be unsuccessful in making the mechanism unless you are a watchmaker. It would be cheapest to buy what you want.—A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61375.]—**Dispensing Chemist.**—Write to the Secretary of the Pharmaceutical Society, London, for the rules as to examinations and admission. You should also try to read the *Chemist and Druggist* weekly; you will find from the examination subjects the course of training necessary.—B.SC., Plymouth.

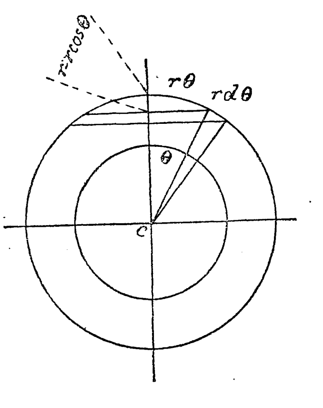
[61378.] — **Mechanics.** — The total pressure on the pair of gates $= \frac{10 \times 6^2 \times 62{\cdot}5}{2} = 11250$

$\frac{11250}{2}$ = pressure on one gate. As centre of pressure is one-third of the depth from bottom—viz., 2ft., the gate between the hinges can be treated as a loaded beam, with 5,625lb. at distance of 1ft. from lower hinge, ∴ pressure on lower hinge $= \frac{5625 \times 3}{4}$ = 4218·75lb. or 4,218¾lb.—DUD. DUDLEY.

[61363.]—**Decrease of Sun's Heat.**—I am of opinion that the reason of the decrease of the sun's heat when it is near the horizon is due to the

density of the atmosphere, which has a much greater resisting power to light and heat when the sun's rays strike through it horizontally, than when perpendicular. I am not of the opinion that there is an agency of any kind to transmit the heat or light from the sun; but that it is the absence of resistance is the reason why we are subject to its effects: otherwise the heavens would be much more luminous at night.—WILLIAMS.

[61378.]—**Mechanics.**—The second question in this query, although not addressed to me, gives us such a neat little problem in the integral calculus, that I cannot resist sending my solution of it. It is to show that when a hollow sphere is filled with water (or other liquid) the total pressure against the inner surface caused by gravitation is equal to three times the weight of the water in the sphere. I will use the polar system, which has always attracted me by its extreme elegance. The outer circle in the figure represents a section of the hollow sphere whose radius is r; the inner circle is supposed to have a radius equal to unity, which may be 1ft. or 1in., or other unit. θ is an arc on the inner circle which, as the radius sweeps round from a vertical position above the centre, to a corresponding position below the centre, varies from 0 to 180° or π; the corresponding arc on the outer circle will therefore be $r\,\theta$. Now, when the radius is in any position, such as is shown in the figure,



suppose the arc θ to be given a very minute increment $d\,\theta$, then on the outer circle this will be $r\,d\,\theta$. We can then suppose a ring to be marked out on the inner surface which is shown by the two horizontal parallel lines drawn near together; the width of this ring will be $r\,d\,\theta$, and its radius when $d\,\theta$ is infinitesimal will be r sin. θ; the area of this ring will therefore be $2\,\pi\,r$ sin. $\theta \times r\,d\,\theta$, or $2\,\pi\,r^2$ sin. $\theta\,d\,\theta$. Now if we were to integrate this expression, we should have the sum of all these rings from 0 to π, which would give us the surface of the sphere, or $4\,\pi\,r^2$; but we require more than this—viz., the pressure on that surface. Suppose p to represent the pressure of water on a surface equal to unity, and of depth unity, say on 1 square foot and depth 1ft., then the pressure on any other surface, and for any other depth, will be p multiplied by the area of the surface and by the depth; hence the pressure on the ring (the area of which is given above) will be given by multiplying that area by its depth below the highest point of the sphere and by p, or by $(r - r \text{ cos. } \theta)\,p$. Hence the expression $2\,p\,\pi\,r^2 \text{ sin. } \theta\,(r - r \text{ cos. } \theta)\,d\,\theta$ represents the pressure on one of the rings for any value of θ between 0 and π. The whole of the internal pressure will therefore be—

$$2\,p\,\pi\,r^2 \int_0^\pi (r \text{ sin. } \theta - r \text{ sin. } \theta \,.\, \text{cos. } \theta)\,d\,\theta.$$

The integral of the first term is $-\,r$ cos. θ, and the integral of the second term is $-\frac{r \text{ sin.}^2\,\theta}{2}$, as this latter vanishes both when $\theta = 0$ and $\theta = \pi$, it may be discarded, and we have only to find the value of $-\,r$ cos. θ between 0 and π. When $\theta = 0$, the value of this is $-\,r$ (as cos. of $0 = 1$), and when $\theta = \pi$ its value is $+\,r$ (as cos. of $\pi = -\,1$), the former must be subtracted from the latter, so the result is $2r$; multiply this by the constants outside the sign of integration, and we get the final result, total internal pressure $= 4\,p\,\pi\,r^3$. Now we know that the contents of a sphere are $\frac{4\,\pi\,r^3}{3}$, and as we have taken p as the pressure on one square foot for a depth one foot, p will be the weight of a cubic foot of water; hence the weight of the water in the sphere is $\frac{4\,p\,\pi\,r^3}{3}$, hence the pressure is three times the weight of the water.—M.I.C.E., Bath.

[61380.]—**Engine.**—I wrote 4in. by 6in., not 12in. by 8in. as appeared on p. 440. With a smaller diameter of cylinder, I should expect frequent stoppages.—A. F. SHAKESPEAR, Lüttichaustr. 14 III., Dresden.

[61382.]—**Instantaneous Exposures.**—The cause of your failure is that you are mistaken in the idea that the plates are under-exposed: they are over-exposed. With a R.R.S. lens, drop-shutter, summer, and mid-day sun, you require the smallest stop, and not full aperture, for any rapid plate; that is my experience in identical conditions.—B.Sc., Plymouth.

[61379.]—**Trocadero Organ.**—I have much pleasure in giving "C. C." the specification of the organ erected by M. Aristide Cavaillé-Coll, in the Salle des Fêtes of the Trocadéro:—

MILVERTON.

[61384.]—**Steam.**—If you can alter the action of your fan so as to suck from the wooden shaft instead of trying to create an air blast, you may perhaps succeed. If unable to do this, put a $\frac{1}{4}$in. steam jet in instead of the air blast; this, however, takes a good bit of steam, and you would find a suction fan best.—T. C., Bristol.

[61384.]—**Steam.**—"Perplexed" will find the best remedy in causing the fan to exhaust from the uptake over the boiling pan; the fan should be of the Blackman type, and, say, 24in. diameter. The uptake must, of course, be made of sufficient area to supply the fan freely. This method of clearing the air is now very generally employed; take off the vapour as near to the pan as possible.—FRANCIS M. ROGERS.

[61386.]—**Focus of Lenses.**—The actual focal length of a single lens is the distance from the back surface to the principal focus (or burning point), measured usually in inches and fractions of an inch. The back focus of a doublet is the distance from the back surface of the back lens to the principal focus; but the equivalent focus is the actual focus of a single lens, which would form an image of a given object at a given distance of exactly the same size as the doublet forms. For the simplest method of determining this see Dallmeyer's pamphlet on "The Choice and Use of Photographic Lenses."—T. PERKINS.

[61388.]—**Browning Gun-Barrels.**—I fear I can't add much to what I have already said on the subject in the "E.M." As an amateur the present weather is all against you; but how is it you got on all right with the single and failed in the case of the double? But try again, and pay very strict attention to the following:—Be sure you remove all traces of grease from your barrels, and keep any grease away from your appliances. Don't have much liquid in your sponge. After dipping the sponge in the mixture, squeeze it with your fingers so as to take some of the liquid out. When applying the mixture, take long, even strokes from muzzle to breech; no pressure required—as light as you can. Try and put the mixture on even—not thick in one place. You must give the necessary time to dry between the applications—viz., twelve hours from first coat to second, and six hours between each coat after; from four to six coats should do. You must or should have a room or shop where you can get a temperature of not less than 60° Fahr., but between 70° and 80° will be much better. If you have no such convenience,

and you have to merely do your drying in front of a kitchen fire, you must keep your eye on the barrels and see that they don't get hot—in fact, not even warm; never apply the mixture while the barrels are warm. If the mixture does not dry evenly on the barrels you will have them streaky and patchy. The barrels should be dipped into the boiling water just for a second or two. The more they are scalded the darker they get. If you have an iron or tin trough for your hot water you will be able to do your scalding regular; but if you scald your work from a kettle-spout, then most likely you will scald one part of your barrel more than another. The part most scalded will be darker; so if you do the scalding from a kettle-spout you must endeavour to distribute the water as evenly as possible. Your wood plugs can have had nothing to do with your failure. Gun-barrel browning is one of those processes which if not carried out according to "Cocker" must fail. I would advise you to scratch-card your barrel before scalding; do it lightly, and scratch again after scalding. Have the plug in the muzzle end; not that it will make any difference in your work. If you have a trough, before scalding remove the wood plug. Get two pieces of stout wire, say about 16in. long, bend one end 1½in. or so at right angles, insert the short bends one in each end of the barrel, using the long ends as handles. Thus you can lift your barrels in and out of the water in a horizontal position. If you scald with a kettle, have a plug in each end, so that you can reverse and pour water on from muzzle to breech and breech to muzzle. Don't leave plug in while barrel is getting dry after mixture is put on. This has nothing to do with the browning; but leaving the plug in may cause rust on the inside, where it is best away. You may at any time handle your barrels with a piece of clean rag, not necessarily clean, but free from grease. Grease is death to browning. The best method of removing grease from barrels, and the one recently adopted for Government rifles, is to boil the barrels for ten minutes in strong soda water, not using the same water for two sets of barrels. This process is cleaner and better than lime; ½lb. of soda to a gallon of water will do: more soda would do no mischief. After taking barrel out of soda water it would be as well, while yet warm, to rub down with scratch-card; then let the barrels get cool before putting on mixture. Now I hope you will succeed.—ARMOURER.

[61389.]—**Wimshurst Machine.**—It is not possible to say where "Hendon" is wrong, without having the machine to examine; but let him attend to the following:—(1) See that more than eight sectors be on each plate; (2) see that the plates run not more than ¼in. apart; (3) see that the front driving band is straight, and the back one is crossed; (4) make quite sure that each of the brushes is in actual metallic contact with the other and with the sectors (even a thin coating of lacquer is fatal); and, lastly (5), see the brushes rightly placed—viz., on the front plate the lower brush is to the right hand of the stanchion of stand, the top brush to the left-hand side; the brushes at the back to be at about right angles with the front brushes and rod. If he attends to these matters, and then turns the driving-handle, it is quite certain that he will obtain self-excitement. The tubes will answer very well; but he should put resin plugs into the ends of them to prevent damp and dust entering. He should read the work by Silvanus P. Thompson to find a number of useful experiments, the details of which are very clearly given. —J. W.

[61390.]—**Engine Query.**—The "model" inquiries generally omit to say the speed engine is required to run, and if only to be looked at or to do some real work. This engine to do the latter would require a boiler, say, vertical, 20in. high and 15in. diam., with internal firebox, and of $\frac{3}{16}$in. plate, and work at 50lb.—T. C., Bristol.

[61391.]—**Soldering.**—"Galen" apparently thinks he is to put the copper-bit into a pailful of soldering-fluid. Here's one way of doing it: Make a shallow hole in a bit of brick; put some bits of solder in the hole, and on them drops of soldering fluid. When copper bit is hot and cleanly filed, immerse, and the solder will run all over the clean part unless it is prevented. The cheapest way to make the fluid is to procure clean scrap zinc, and dissolve as much as possible in commercial spirits of salt. If you want to increase the bulk you can add water. Is any flux required in coating iron with lead except the usual preliminary dip in the hot grease bath?—REGEL.

[61391.]—**Soldering.**—"Galen," with a little experience, will be able to tin and solder very well. Buy, say, 1lb. of spirits of salts, which costs about sixpence, pour as much as you want into a jar—a jam pot will do—and now you want to do what is termed killing it; that is, cut up some small pieces of zinc and drop in the spirit, it will then begin to boil up; keep on adding the zinc till it will boil no more, at the same time keep it away from all bright iron or steel work, as well as your nose. Now put your iron in the fire and make it nice and hot, not red-hot mind; then file the face and sides bright, then dip quick into the spirit, and out again, then press the end of a stick of solder on to the face of the soldering iron, dip again into the spirit, then you will have a bright tinned surface to begin work with. All work to be soldered must have a clean bright face to it, by filing or scraping; then apply the spirit—a penny gum brush will do. It will answer the purpose of galvanising as well as tinning, on small jobs. Pleased to answer again, if required.—PICKLOCK.

[61393.]—**Electric Indicator.**—TO MR. CONRY OR MR. BOTTONE.—Not knowing this make I am unable to advise.—S. BOTTONE.

[61394.]—**Dynamo: Cast-Iron Bed.**—TO MR. BOTTONE.—The use of a cast-iron bed would short-circuit the magnetic field of this dynamo, and render it totally inactive. You may turn the machine upside down, like this U, and use a cast-iron plate, to which the bent ends of the F.M.'s may be bolted, if it be desired to drive the machine by power; but by no means let the pole pieces be in any way connected together by iron. A dynamo double the size would have about 32 times the power. The size of the wire must also be doubled; its weight must be quadrupled. Speed about 1,600 revs. It will light an arc-light well of about 1,000c.p.—S. BOTTONE.

[61395.]—**Legal.**—This query cannot be answered without an inspection of the will; but probably the trustees are right. Suppose (which is quite likely) that the property does not vest in C., D., and E. until B.'s death, that the trustees paid C. his share now, and that C. should die before B., D. and E. could claim the whole estate from the trustees, and they might personally lose the money they paid to C. 2. C., D., or E. can make a will if they are of age; but it depends on the period of vesting whether or not it is of any use so far as the grandfather's will is concerned.—B.SC., Plymouth.

[61397.]—**Disposal of House Sewage.**—Use an earth closet.—OHMI.

[61397.]—**Disposal of House Sewage.**—This is a wide query, and to answer it one would require to see the house, its position, and surroundings. A cesspool well built and cemented water tight is probably the answer.—B.SC., Plymouth.

[61398.]—**Electric Battery.**—If you use two boxes precisely similar to the one figured and described at p. 435 of the ENG. MECH. for Jan. 14, 1887, you will obtain the desired results. The size of plates described by you—viz., 5in. by 2in.—will do very well. Each box should contain four cells. As the exciting fluid, try my receipt—viz., chromic acid, 3 parts; sulphuric acid, 3 parts; water, 17 parts. Not every 10c.p. lamp can be lighted with 8 cells, as they give only 16 volts; but I have been using a very good 10c.p. lamp, which takes only 12 volts to work it.—S. BOTTONE.

[61399.]—**Leclanche Batteries.**—Yes. It would cause them to run down much sooner.—S. BOTTONE.

[61399.]—**Leclanche Batteries.**—I have known cases where the porous pots have been cracked, and with no apparent detriment to their working capabilities. Are all the terminals clean? Perhaps the cheapest way is to throw the defective cells on one side and replace by new ones.—J. H. H.

[61399.]—**Leclanche Batteries.**—The bursting of the porous jar should not be injurious to the working of the battery, unless the contents of the jar are coming out and mixing with the liquid; in this case the action would certainly be feeble. Either get new jars, or cover the burst part with a patch of cloth tied round; of course, if a quantity of the manganese has been lost the cloth will be no remedy so far as the regaining of strength is concerned.—BOBADIL.

[61399.]—**Leclanche Batteries.**—The bursting of the porous cells would certainly be injurious to the working of the battery. You may possibly have a partial or actual short-circuiting of your line wires. Try new porous cells, and run a fresh wire from battery to bell (well insulated). See that extra contacts of the bell are clean, and that the holes or tubes at the top of the porous cells are quite clear.—LANCASTER.

[61399.]—**Leclanche Batteries.**—Salts of ammonia form in the pores of the cell. You will probably find it work much better now, as the porous cell was probably clogged. Tie round it a piece of blotting-paper with string, and then soak in warm water for a time, and most likely all will be well. Mind, though, no carbon or manganese gets in the outer cell with the zinc, or great local action will take place. See Roberts's paper on Batteries, *Journal* of Soc. of Tel. Eng. Vol. VI. p. 257.—AN A.S.T.E.

[61399.]—**Leclanche Batteries.**—The bursting of porous cells should not do the battery any harm; but if the cells have not been allowed to become dry after having been in use for some time, I should be inclined to think they were bad and fairly worked out. I have for some time discarded the above batteries with porous pots in favour of a large cylindrical compound block, said to consist of carbon, manganese peroxide, and copper oxide, the whole being mixed into a plastic mass and put together under pressure. The resistance of this cell is less than half that of cell same size with porous pot. If your battery is in the mine, then it will always give you trouble, unless your circuits are thoroughly insulated; and in collieries this is the exception not the rule.—OHM.

[61400.]—**Electric Light.**—A small turbine would best meet this case, and estimating its efficiency at 60 per cent. would give off, say, 1½H.P.; the rate of speed would, however, be exceedingly high, and if the water be gritty, a small wheel would soon cut out. Cost about as under:—

Turbine without flume	£20 0 0
Shunt dynamo for, say, 10 lamps of 20c.p.	17 0 0
Lamps, 5s. each (Swan)	2 10 0
Leads, 9d. yard, switches, &c., say, 50s.	2 10 0
	£42 0 0

If arc lamps be employed, say 2,000 candles nominal. —F. M. ROGERS.

[61400.]—**Electric Light.**—Is "Colliery Manager" sure about the particulars he gives? 1,500 tons of water per day of 24 hours (?) = 1 ton per minute, or about 36 cubic ft.; then by Molesworth's formula, 36ft. by 40ft. head × ·001892 = 2¾ *theoretical* horse-power nearly. Thirty to 40 per cent. of this will be lost in the wheel or the turbine, and about 20 per cent. of the remainder in the dynamo, besides loss in the leads and from other causes, so that the electricity available at the works will finally be very small indeed. However, I would not deter "Colliery Manager" from laying down the necessary plant, and if the quantity of water in cube feet per minute is different to that stated, it alters the case altogether. He had better get an estimate from some reliable firm as to the cost of the wheel or turbine, and the probable horse-power (actual). I shall then have much pleasure in giving him a rough estimate of the cost of plant and its maintenance, either on the arc or incandescent systems, whichever he purposes to use.—J. H. H.

[61400.]—**Electric Light.**—You seem to have a large amount of power available—unless mistaken, something like 4,000H.P., a portion of which diverted from the main fall might possibly suffice, and be easily utilised for lighting your works, and for motive power should you require it. It would, I think, be best for you to give particulars of the maximum number of lamps (arc or incandescent) you would require, with approximate candle-power, exact distance from available power—that is, where the water motor and dynamo can be placed to lamps. You would then, no doubt, get some reliable information. If you will advertise your address in "Address Column," I shall be pleased to communicate with you, and give you all the information that I can.—LANCASTER.

[61400.]—**Electric Light and Water-Power.**—With a good turbine a fall of 10ft., with a discharge of 180 cubic ft. of water per minute, gives about 2½h.p. This is just about what your fall would give you if I have understood your statement rightly. Now 2½h.p. would give about 400 c.p. if employed for incandescent lighting, or 1,000 to 1,500 if used for arc light. The requirements would be turbine, dynamo (or two, one for reserve), belting, cables, leads, lamps, holders, brackets, switches, fusible plugs. Total cost of plant should not exceed £200 at the outside. Maintenance, with renewal of lamps, oil, waste, labour, interest, or plant at 5 per cent.; depreciation of turbine and dynamo at 10 per cent.—say, £50 per annum. Of course, this is only a very rough estimate.—S. BOTTONE.

[61400.]—**Water Power for Electric Light.** —With 1,500 tons of water falling 40ft. in 24 hours you have about 28H.P. regularly, and you ought to be able to get about 20H.P. with a good turbine, and from this at least 150 incandescent lights, each 60 watts, and about 16 to 18c.p.: or, if you want arc lights, then you could have 10 lights of about 1,000c.p. each. If you will say which lighting you wish to do, then you might get more information. Of course you would require to carry the whole of the water down a pipe from head to bottom of fall. Could you carry wires overhead, or must they be underground? If all was erected to the works, could arrange to use the power during the portion of day when lights not required to drive a motor. Unless you could do this, it would be expensive in maintenance, and for the few hours per day during which lights would be required; but you might take current into workings if not fiery, and use it either for haulage or lighting—or perhaps both.—OHM.

[61403.]—**Renovation of Violin.**—If your

violin has ever been a good one, you should limit the scraping operation to, say a ship's bottom, and remove the offending varnish by means of methylated spirits. Use French polish, with the use of as little oil as possible, as it would injure the tone. —A., Liverpool.

[61406.]—**Glow Lamps.**— Four cells coupled up in series will be ample. The positive pole is the one starting from the graphite, the negative the one coming from the zinc. Experimentally, you can prove this by letting both wires dip in a solution of copper sulphate. The negative pole will become coated with metallic copper, the positive simply gets corroded.—S. BOTTONE.

[61406.]—**Glow Lamps.**—As usual, see back numbers, and be a "Juvenile Ignoramus" no more. Four or five pint bichromes would light a 5c.p. lamp for nearly an hour, when they would need to be recharged. But unless the plates are kept in motion, or liquid stirred, or something of that sort, the light falls off very rapidly. Connect the carbon of cell A to zinc of cell B, and carbon-cell B to zinc cell C, and so on. Place both wires to the tongue to find which is + and which – and the one that tastes sour is the positive.—IOTA.

[61406.]—**Glow Lamp.**—A 5c.p. lamp of low resistance should be lit with four or five pint bichromate cells; charged with the usual bichromate solution, however, they will not work for a couple of hours. The best charge will be chromic acid, in regard to which you will find much information in recent back numbers. The negative pole of a battery is always the zinc, the positive pole the carbon; but you should get a text-book and read this up. Connect the cells in series, that is, carbon to zinc, carbon to zinc, all through, and lead a wire from zinc in first cell, and from carbon in the last to the lamp.—BOBADIL.

[61407.]—**Glass Spinning.**—I remember seeing this at the Polytechnic, and the wheel went 200 or 300 turns a minute. I know nothing about the quality of the glass rods; but the flame of lamp was large, and worked by a foot-bellows. I rather think you may see it at the new "Palace" near Battersea Park.—T. C., Bristol.

[61407.]—**Glass Spinning.**—This is very easy after a little practice. My wheel is a foot in diameter, and revolves at the rate of a mile a minute. I find the faster you spin the finer the glass. The wheel should be slightly moistened to start with. Ordinary rods of soft glass, about the size of a cedar pencil, are the best. I use a benzoline blowpipe flame with a foot blower, but would prefer gas if I could get it. The flame should be pointed and steady. I have seen glass-workers in Tottenham Court-road, where they sometimes take a room and charge so much to go in and see them. I shall be glad to give "S. B. B." any further hints he may require.—M. R. C. S.

[61408.]—**Violin Query.**—It is very probably caused by some part of the back, or the belly, being loose; this usually takes place where the chin comes into contact, or the hand as it shifts, and is caused by the perspiration decomposing the glue; if on tapping it be found to be loose, insert the blade of a penknife gently; then dab in some good thin hot glue, work it well in, and apply a clamp.— A., Liverpool.

[61409.]—**Violin Query.**—Try the breast and back whether they are loose; try well, for although you may not be able to see it, they may be partly loose. If they are intact, the bass bar or finger board may be the cause.—J. H. SCHUCHT.

[61409.]—**Coating Springs with Copper.**— Here is a recipe for coppering solution without a battery, which I have found to answer well for articles of iron:—Nitrate of copper (dry), 4oz.; cold water, 1 gal.; sulphuric acid, 12oz.; sal-ammoniac (powdered), 4oz. Smaller quantities may be made up if the proportions are adhered to. —BOBADIL.

[61409.]—**Coating Springs with Copper.**— This question has been frequently answered. The ordinary "sofa springs" are coated with copper by first cleaning them and then immersing in a solution of sulphate of copper. Gore gives several recipes, the best of which is, perhaps, that in which the iron previously cleaned by immersion in a mixture of nitric acid 1, hydrochloric acid 50, is placed in a bath of 10 parts of nitric acid, 10 parts chloride of copper, and 80 of hydrochloric acid. Immerse several times, and rub with woollen cloth between each immersion. Another good process is to dissolve in 1,000 parts of water, 150 of Rochelle salt, 80 caustic soda, and 35 of sulphate of copper. Clean the iron by immersion in dilute sulphuric acid, washing in water and in solution of soda. Then scratchbrush, wash, and immerse in above solution, hanging the articles on zinc wires. There are many recipes of the kind; but it should be noted that the simple process of dipping in the sulphate solution gives a coat that will not stand handling.—SAML. RAY.

[61410.]—**Medicinal Action of Dynamos.**— To the best of my experience (now extending over more than 20 years), the dynamo, unless its current is passed through the human body, is absolutely without action upon it. Owing to the proximity of the poles to one another and to the armature, very little magnetic action is excited on surrounding bodies, and this little only on those in very close proximity, owing to the fact that the effects diminish as the cube of the distance.—S. BOTTONE.

[61410.]—**Medicinal Action of Dynamos.** —Various persons have told "snake stories" about dynamos, but certainly "the Dispenser at the Free Dispensary, Lydney," in the yarn related on page 441, has fairly made the highest possible score. It is, however, a pity that Dr. M. (why is the name not given?) did not investigate the matter further; he might then have found that, while series-wound dynamos made people irritable, shunt-wound machines had a soothing effect, and that separately excited dynamos induced devotional and reverential feelings. Did Dr. M. visit the large building (why are name and place omitted?) on the first of April? — WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[61411.]—**Drilling.**—Fasten the upper portion of a slide-rest to table of machine, and remove the screw of slide, and instead of this fasten a length of flat iron to slide. You can now drill this piece of iron the same distance apart as the holes are required to be. Now make a lead chuck, shape of lower part of castings, and fasten to slide, so that you can drop the castings into chuck for drilling. You can at same time fasten a template to slide so that a collar on drill or spindle comes down to it to regulate the various depths required. All you will now have to do is to drop a taper pin in the holes of flat bar and a hole in table, and bring down the drill until collar stops it on the notched template.—T. C., Bristol.

[61412.]—**Twin Screws and Paddle Engines.**—The increased power of manœuvring ships with twin screws or disconnected paddles arises from the fact that one propeller can be driven ahead while the other drives astern. The ordinary disconnecting clutch is used in many tug-boats; but some, I believe, have a disc on the intermediate shaft instead of a crank arm, and that disc is fitted to the shaft with feathers, so that it can be drawn on the shaft clear of the crank-pin when it is desired to disconnect. I think examples will be found in Bourne's works. NUN. DOR.

[61414.]—**Electro-Motor.**—To MR. BOTTONE and E. CONRY.—Put about 2oz. of No. 20 on armature, and 2lb. No. 20 on fields. Six bichromates will cause it to drive a sewing-machine. Yes; one by Urquhart, 7s. 6d.—S. BOTTONE.

[61418.] — **G.W.R. Engines.** — The largest driving wheel on the G.W.R. is 8ft. These are found on the Great Britain class, originally built about 1847. Of the four B. and E.R. 10 wheeled double bogies, with 9ft. driving wheels, which came into possession of the G.W.R., one was wrecked in an accident near Bristol in 1876; the three remaining ones were then altered into 8 wheeled tender engines, with a leading bogie and 8ft. driving wheels, and are, I believe, still running. No. 10 is the only one yet built of a new class; she somewhat resembles No. 9, but has not outside eccentrics. Her driving wheels are 7ft. 8in.; she is a single 6 wheeled engine with dome. The drivers speak very well of her performance.—T. PERKINS, M.A., Shaftesbury.

[61419.]—**Loco. Wheels.**—I have been told that there was once made at Crewe a loco. with 10ft. 6in. drivers, which never moved out of the shed. I should very much like to know if this is true. I suppose the necessary height of the centre of gravity militates against drivers over 8ft. I saw it once stated that to obviate this an engine was once erected with very large single drivers on the tender. This seems too absurd. I should imagine the Caledonian 8ft. 2in. singles are the largest narrow-gauge drivers out, unless L. and N.W.R. loco. "Cornwall" is still on the road. Perhaps the readers of the "E. M." may be interested to know the largest drivers of the more important railway companies:—

L. and N.W.R. "Cornwall"	8ft. 6in.
C.R.	8ft. 2in.
G.N.R.	8ft. 1in.
M.R.	8ft. (?)
L. and N.W.R. singles and G.E.R.	7ft. 6in.
G.W.R., N.E.R., N.B.R., S.E.R., L. and S.W.R., and G. and S.W.R.	7ft.
L.B. and S.C.R.	6ft. 9in.
L.C. and D.R., L. and Y.R., and M.S. and L.R.	6ft. 6in.

As regards the Midland, I don't know whether the new singles are out yet. I should very much like to know this, and if so, what road and load they are working. The Metropolitan and District Railway's coupled tanks are, I believe, 5ft. 9in.; I won't be sure. The above sizes are on narrow-gauge lines. I believe the largest broad-gauge single drivers run between Bristol and Exeter, and are about 9ft. 2½in. in diameter. I would like to know whether they have names or numbers; I think the latter.—SEVERN TUNNEL.

[61421.]—**Case-Hardening.** — If "Querist" has many set-screws to case-harden he will probably find it quickest to heat them up to blood-red in an iron box containing bits of leather, or horn, or bone-dust, and then quench in cold water. If, however, he has only one or two to do, it will be found less trouble to heat the screws. After polishing to a bright red, rub them or dust them with prussiate of potash (poison), allow to cool to a dull red, and quench.—FIVE MILES FOUR.

[61421.]—**Case - Hardening.**—If your screws are made of Bessemer steel they will not be required to be case-hardened, as you term it, as that instance only applies to wrought iron; but you can harden them all the same. Put the screws into a short piece of gas-pipe, about 7in. or 8in. long; bung both ends up with a piece of clay; put it in the fire and heat to a cherry red; then tip them into oil; then polish the heads and place them on a red-hot plate till they turn blue; then tip into oil again.—PICKLOCK.

[61421.]—**Case-Hardening.**—I was told by a manager of a large printing machine shop how to case-harden iron and give a perfect coating of steel which will harden like ordinary steel. Take your iron (good soft wrought iron) and make your screws or any other small article; finish off except polishing. Now you want every finished part to be of steel. Proceed as follows:—Take some black marble and some oak charcoal (oak best, but any hard charcoal will do); pulverise both not too small. Take an iron vessel much larger and much deeper than the article to be steeled (not stolen), mix the pulverised black marble and the charcoal together, put a good layer of the mixture (if you like add other carbonaceous matter, such as leather, or what you like, as long as it is carbon-yielding with heat) on the bottom of the iron vessel, then insert the article, then cover deeply with the same mixture, then, if a lid is handy for the vessel, put it on; if not, put some fireclay on top, as, or in lieu, of the lid to the vessel; then put the vessel into the hottest heat you can get (a Fletcher's muffle or air furnace will do the trick), and keep the whole at a good heat (white, if possible) for as long as you can afford time and cost. The result, according to heat and time, will be that every part of the article will be steel on the outside to a certain fixed depth, equal all over. The steel may be ·01 thick, or ·1, or ⅛th thick. Now test this. Take the article, say a round bar, cut it off at an angle of 45; heat, quench, temper as of steel, polish, and you will see the ring of steel. Tried and vouched for.— R. S. T.

[61423.]—**Strength of Materials.**—The torsional strength of iron rods is proportional to the cube of the diameter, and in the case of hollow rods the strength is found by taking the difference of the cubes of the internal and external diameters. Hence, taking the original strength of the shaft as 1,000, the strength will be reduced to 936 when the 4in. core is removed. The amount of weight removed will be proportional to the squares of the diameters, for it will amount to about one-sixth. A cubic inch of cast iron weighs about 1,820 grains.— WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[61423.]—**Strength of Materials.**—Areas of circles are to each other as the squares of their diameters. $\therefore \frac{4^2}{10^2} = \frac{16}{100} = {\cdot}16$, or $\frac{4}{25}$ = fraction of weight removed. Torsional moment of resistance $= \frac{\pi}{16} f a^3$

$f = 4500$ for cast iron; d = diam. of shaft.

For 10in. diam. $= {\cdot}19625 \times 4500 \times 1000 = 883500$

For 4in. diam. $= {\cdot}19625 \times 4500 \times 64 = 56549$

$\therefore \frac{56549}{883500} = {\cdot}064 = \frac{2}{31}$ = fraction of strength to resist torsion removed. The weight of a cubic inch of cast iron varies from ·252 to ·273lb.—ELAG.

[61423.] — **Strength of Materials.**—The weight of round iron varies as the square of the diameter, and of a hollow shaft is that of a solid shaft, full size, less the weight of a shaft the size of the hole—that is as $10 \times 10 - 4 \times 4 = 100 - 16 = 84$, consequently 16 per cent. of its weight is removed. The actual area $= 84 \times {\cdot}7854$. The strength of a shaft varies as the cube of its diameter, and the relative strengths are therefore $10^3 = 1000$, and $10^3 - 4^3 = 1000 - 64 = 936$, or as 100 : 93·6. You will see by this that although the shaft is 16 per cent. lighter, it is only 6·4 per cent. weaker than a solid shaft 10in. diameter, owing to the better position of the material to resist the strain. Practically, you may take ¼lb. as weight of a cubic inch of iron, either wrought or cast; it is a little less really.—T. C., Bristol.

[61423.]—**Strength of Materials.**—Naturally, the weight of two bars of the same length varies

as the areas of their cross sections. The area of a 10in. cylinder is 78·5398 sq. in.; while the area of a 4in. cylinder is 12·5664 sq. in.; so that the area of the hollow cylinder whose outside diameter is 10in. and inside is 4in. will be 65·9734in., so that the weight of the 10in. hollow cylinder will be $\frac{65 \cdot 9734}{78 \cdot 5398} = \cdot 84$ (nearly) of the weight of the 10in. solid cylinder, taking equal lengths. As to the reduction of its capacity, when hollowed out, for resisting a torsional stress, I cannot find any reliable formula. The formula generally given gives the ratio of strength of a hollow cylinder to that of a solid one, the areas of the cross sections of both being equal; for instance, a hollow cylinder 12in. external diameter and 6⅝in. internal diameter possesses the same area of cross section as a 10in. solid cylinder (78·54 sq. in. nearly), but is very nearly 1·58 as strong to resist a torsional stress. Weight of 1 cub. in. of cast iron varies, with the manufacture, from ·253lb. to ·273lb.; while an average value—i.e., the one generally used in finding weights of castings—is ·26lb.—SEVERN TUNNEL.

[61424.]—**Model Steam-Engine.**—You cannot do better than buy a set of castings for, say 1in. bore, at about four shillings, as advertised by Lee in "Ours," and most of your queries will be answered in endeavouring to fit them up.—T. C., Bristol.

[61425.] — **Oak Cantilever.**—Taking your figures as to strength, and a factor of safety of 4, the lever would require to be = (using 6 instead of 5·83) $1120 \div (6 \times 9^2) = 1120 \div 486 = 2 \cdot 3$in., or, say 2½in. wide. This is taking the breaking weight of a cantilever 1ft. long as 140lb., and, consequently, if 6ft. long and 1in. square, as 23·31b., or safely as 5·83lb.—T. C., Bristol.

[61425.]—**Oak Cantilever.** — It is generally taken as a rule, that the relative strength of solid rectangular beams varies directly as the square of their depths, and directly as their breadths, and inversely with their length; hence it becomes, in cases of this kind, simply compound proportion:—

x	:	1 breadths in inches
280	:	1120 weights in pounds.
6″	:	72^2 lengths reduced to inches
9^2	:	1^2 depths in inches
1	:	4 margin of safety

$$x = \frac{1 \times 1120 \times 72 \times 1^2 \times 4}{280 \times 6 \times 9^2 \times 1} = 2\tfrac{3}{8}\text{in. nearly}$$

—DUD. DUDLEY.

[61425.]—**Oak Cantilever.**—Using the formula $W = \frac{K\,B\,D^2}{L}$ (cwts. and inches), the breadth of your beam, using a factor of 4 (i.e., a breaking load of two tons), is 2·37in. for English oak, when K has a value of 15cwt.; and should it be African oak, where K = 22cwt., its breadth would be 1⅝in. But I would prefer using a beam having less depth, and therefore requiring a greater breadth than 2⅜in., as with so long a cantilever I should be afraid of an absence of rigidity sideways, in which case it would twist sideways and probably rupture. Say you used a beam 7in. deep, its breadth would then be $3\frac{15}{16}$in. (English oak), and there would be plenty of transverse rigidity probably. Taking the depth of beam (English) as 9in., however, the deflection under a ½ ton load is about $\frac{9}{16}$in., I think. These results will be found to agree with the assertion in the latter part of your query, taking the material to be English.—SEVERN TUNNEL.

[61425.]—**Oak Cantilever.**—

$$\left.\begin{array}{l} L = \text{length of beam} \\ B = \text{breadth} \\ D = \text{depth} \end{array}\right\} \text{in inches}$$

W = breaking weight in pounds
K = greatest bending moment

$$\therefore\ W = \frac{K\,B\,P^2}{L}$$

$$K = W\,L = 6 \times 280 = 1680 \text{ (from small beam)}$$

$$\therefore\ B = \frac{L\,W}{K\,P^2} = \frac{72 \times 1120}{1680 \times 81} = \frac{80640}{136080} = \cdot 593\text{in.}$$

Multiplied by factor of safety 4 = 2·372in. Or it may be reasoned out without formulæ thus:—If a beam 6in. long by 1in. square breaks at 280lb., a beam 72in. long by 1in. square would break at 23·31b.; and as the strength of a beam varies as the square of the depth, a beam 72in. long by 9in. deep by 1in. broad would break at $23 \cdot 3 \times 9^2 = 1889$lb., then breadth to break at half a ton $= \frac{1120 \times 1}{1889} = \cdot 593$in. Multiplying by 4 as before gives 2·372in. = breadth required.—ELAG.

[61428.]—**Legal.**—(1) A. could not legally refuse to deliver the key to B. after having sublet the house to him on the ground that he wished him to buy a "small garden valuation." (2) A. could not let the premises again after having let them to B. (3) B. can only recover the money he paid to A. if he shows that A. got it on false pretences. (4) B. can recover loss actually sustained by reason of A. refusing him the key.—B.SC., Plymouth.

[61431.]—**Dynamo for Plating.**—Put 4oz. No. 16 on the armature, and 4lb. No. 20 on the fields. Connect up as a shunt machine.—S. BOTTONE.

[61438.] — **Measuring Cloth.** — "Factory Worker" can't get a simple rule for finding the length of cloth on a roller; but he can make a table which will be much more accurate, and give him and others less trouble, by putting on his 100 yards, measuring it off yard by yard, and noting the circumference; or what would be still more practical, put a disc on one side of his wheel, and mark on it the diameter attained by each yard with a dot, and, say, a figure at every 5.—B.SC., Plymouth.

[61438.]—**Measuring Cloth.**—The solution of this question will be the same as to find the sum of an arithmetical series, of which the first and last terms and the common difference are given. From the given conditions it will be easily seen that the common difference is equal to $\frac{36}{\cdot 119}$. Now the first given circumference being 12in., if we take C as any other circumference of the roll, also reckoned in inches, the formula for finding the length of the cloth in inches will be—

$$L = \frac{119}{72} \cdot C^2 + \frac{C}{2} - 232.$$

$$\begin{array}{llll} \text{Thus for } C = 24 & L = & 732 & \\ C = 30 & L = & 1{,}270\tfrac{1}{2} & \\ C = 36 & L = & 1{,}928 & \\ C = 48 & L = & 3{,}600 & = 100\text{yds.} \end{array}$$

—MILVERTON.

[61439.]—**Faulty Musical Box.**—Almost all musical boxes make that whistling noise; but it is usually detected for the first time after it has been repaired or cleaned. Most likely a closer observation is made after that operation. The cause of it is this. When a pin of the barrel puts a reed in vibration, another pin comes up before the reed has stopped vibrating, and then it touches the pin several times before they close. In the bass part of the instrument little springs are fixed underneath the reeds; these springs meet the pin first, and by that means the vibration of the reed is stopped before it is touched by the pin.—J. H. SCHUCHT.

[61439.]—**Faulty Musical Box.**—If "Box" will unscrew the steel comb from his musical box he will find under the points of the teeth in the comb little fibres; it is some of them that are either broken, loose, or out of place, and that is the cause of the whistling. His best plan is to take it at once to a practical man, when it will only cost him a trifle to put right. Watchmakers can clean them, put mainsprings, &c., into them; but very few of them can stop the whistling. They generally make bad worse, and either return them unrepairable or they send them to a practical musical-box repairer, and charge you a fabulous sum. In case "Box" does not know how to take the comb off in safety, I may tell him to be sure the mainspring is quite down before he takes the comb off, for if the spring is only wound up a little way, he may do great damage; but it will pay him best to take it to a practical man as it is, for it requires a deal of practice to alter this simple thing.—DUNCAN.

[61441.]—**Notes on the Church Organ.**—TO "C. R. O.," DEVON.—I feel much gratified at the kind way in which you have alluded to my writings on the Organ. With reference to the purport of your query, I have to assure you my quotation, and the copy of the notation from Helmholtz's "Sensations of Tone" (page 33) are perfectly correct. I give you below the relative number of vibrations for each harmonic in the just or untempered scale, from which you will see that so far as the ninth and tenth upper partials are concerned, Helmholtz is correct. The only apparent inaccuracy exists in the seventh upper partial tone, the just b″ flat requiring 1843·20 vibrations, while seven times the number of the vibrations of the prime equal 1,792 vibrations. This last number places the seventh upper partial in the enharmonic diesis, or between a″ sharp = 1777·77 vibrations, and b″ flat = 1843·20 vibrations—

1.	Tenor C =	256	vibrations per second.
2.	Middle c′ =	512	„ „
3.	g′ =	768	„ „
4.	c″ =	1024	„ „
5.	e″ =	1280	„ „
6.	g″ =	1536	„ „
7.	b″ flat =	1843·20 (in just scale)	„
8.	c‴ =	2048	„ „
9.	d‴ =	2304	„ „
10.	e‴ =	2560	„ „

Any further information on this subject, which it is in my power to give, you may command; and I shall be pleased to have any ideas of your own on the question.—G. A. AUDSLEY.

PLUMBERS should be careful not to use lead in contact with oak, unless the latter is perfectly dry and free from sap; otherwise the gallic or acetic acid in the wood will turn the lead into acetate of lead or ceruse.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

QUERIES.

[61442.] — **Weight of Moist Air.** — In Watts' Dictionary, art. "Hygrometry," there is a table calculated on the assumption that the weight of a cubic foot of saturated air at pressure p, temp. t, is equal to (weight c. ft. dry air + c. ft. vapour) $\times \frac{p - E}{p}$; where E = tension of sat. vap. at temp. t. Should this not be "(weight c. ft. dry air) $\frac{p - E}{p}$ + wt. c. ft. vapour"? For 1ft. dry air at p, $t = \frac{p}{p - E}$ ft. at $p - E$, t. This mixed with $\frac{p}{p - E}$ ft. of sat. vap. at E, t produces (Dalton's law) $\frac{p}{p - E}$ ft. sat. air at p, t. ∴ 1ft. sat. air at p t contains $\frac{p}{p - E}$ ft. of dry air (at p, t), and 1ft. sat. vap. If I am right, Watts' table is in error by $\frac{E}{p} \times$ wt. c. ft. vapour. This, at high temperatures is considerable.—L. S. A.

[61443.]—**Ebullition.**—Will some reader explain the following facts? If steam of water is passed into liquid carbon disulphide, or if carbon disulphide vapour is passed into water, a mixture is obtained which boils at 42° C., being 4° C. lower than the boiling-point of carbon disulphide alone.—H. C.

[61444.]—**Dynamo.**—Will Mr. Bottone give me advice how to get out of the muddle I have got in? I have made a dynamo from the description given in his book, but cannot get it to work. When I couple the two brushes up, small sparks appear on the commutator. I have tried commutator with two plates and eight plates, and wound armature with No. 22 s.c. wire, with same result.—STILL IN HOPE.

[61445.]—**G.W.R. Compound.**—I understand that the Great Western Railway Co. are building, or have built, a broad-gauge compound engine, No. 8. Can Mr. Perkins, or any of "ours," give particulars, and, if running, state by what train from Paddington?—COMPOUND.

[61446.]—**Lead Waste.**—I have the opportunity of obtaining a large quantity of lead ashes and sulphate of lead. I shall be glad if any of my fellow-readers will inform me how to extract the lead profitably. Should the stuff be fused, and with what mixture, and would an ordinary iron pot, used for melting lead, be of any use to perform the operation in? I know how to assay lead over at the laboratory; but am unacquainted how to work on a large scale. How can ordinary lead be softened? Are there any cheap books published on smelting, &c.?—J. MONTAGUE JACQUES.

[61447.]—**Sugar in Boiler.**—We put 7lb. of common sugar in the boiler to prevent the scale from clinging to the sides. A few days after, we noticed that the steam emitted from the safety-valve smelt very sour, and since the odour has gone on increasing. Could anyone tell us how to prevent this?—E. A. B.

[61448.] — **Sulphocyanide of Barium.** — I am anxious to obtain a theoretical knowledge of the manufacture on the large scale of sulphocyanide of barium—the most approved and economical method, together with any practical hints. I write this in hopes that, through the medium of your paper, I may obtain the desired information, or be referred to some work treating on the subject.—REGULAR READER.

[61449.]—**To Mr. Bottone.**—Will you kindly say how much wire and size is required on my dynamo of following dimensions of wrought iron: Frame, 18in. long by 6in. wide in centre, 3in. at ends. 6in. high; poles, 5in. long by 1in. thick, with pole-pieces 6in. by 3in. by ⅜in., with brass discs, G ring, 16 gauge iron wire, built up to size 4in. diam., 3in. long, ½in. thick. I have some 18-gauge d.c.c. wire, which I think would do for armature; and kindly say the best way to wind the armature.—A. BAINES.

[61450.]—**Engine Details.**—I have a cylinder for a horizontal engine, 4½in. bore, 9in. stroke, I intend fitting up myself for my own use. Will any able reader oblige by answering the following questions? (1) What length should the connecting rod be? (2) I propose having crank shaft 1⅝in. dia. What should be the dia. of crank and width between shoulders to take brasses of connecting rod? (3) What dia. and weight flywheel? I shall have

to make a pattern for bed plate, but want the length of connecting rod before doing so.—YOUNG BEGINNER.

[61451.]—**Defective Fire Engine.**—Will some of our fellow-readers who have had experience in Merryweather's fire engines help me out of the following dilemma? I have had one to repair, and have got the left-hand engine to work all right; but the right-hand engine stops on the out stroke, and will not return without touching the valve with the hand. Can anyone tell me how to set the valves or the twisted slide bar so as to make it self-acting same as the left one?—ONE IN A FIX.

[61452.]—**Electrical Apparatus.**—I should be much obliged if some of our electrical correspondents would help me to design a switch-board for a small experimental installation. I want to charge nine secondaries from some primary battery, then discharge the accumulators through my lamps. I have five circuits, but only three will be working at one time. I want to take E.M.F. current, &c., by means of switching in the instruments at any time, and require to vary number of secondaries charging. I have plenty of switches and fuses of every pattern, but can hardly see the best arrangement for them. We have not heard much about the Upward primary battery lately. Can anyone say anything of its working, or give details of an installation where it is in use? What would be the best practical means of lighting a house of four rooms and kitchen by electricity? About what would be the probable expense? I see Messrs Shippey's lamps recommended highly; but I have tried and tested a great many different kinds of lamps, and I am best pleased with the new pattern 8 and 10-volt Edison-Swan lamps for primary battery lighting. I should be glad to hear from somebody who has tried them and find what he thinks of them.—ELECTRICAL STUDENT NO. 2.

[61453.]—**Lacquers and Dips.**—TO "IGNORANT." —Please tell me if I can convert hot lacquer into cold. If not, how is cold made? Also, is it possible to make a dip that will turn copper brass colour, and how to proceed in lacquering Florentine colour? I know how to lacquer green of the dip you so kindly gave in No. 1136.—BROSCENICUS.

[61454.]—**Hints on Purchasing a Lantern.**—A society with which I am connected thinks of purchasing a good lantern for use at its meetings. It is to be fitted so as to work with either oil or limelight, to give, say, a 16ft. or 18ft. disc with the latter, and to have a lantern microscope attachment, as well as the fitting for ordinary slides. I should be very much obliged for a few hints on the points to be attended to in purchasing such an instrument; also opinions as to whether it is worth while to have a biunial when the object aimed at is instructing rather than amusement purely.—J. BROWN, Belfast.

[61455.]—**Electric Bells.**—TO MR. CONRY.—I have a large building to fit with electric bells. It is composed of three flats, with a number of rooms on each flat. Over each room will be an indicator. On each flat there will be a special room. In the main hall there will be a 3-hole indicator, with a small bell. When contact is made, one hole will tell which flat, so that the attendant will go there, but the special rooms are to have a larger bell of different tone. Could I connect both bells to the indicator in such a way that only the one required will ring?—J. B.

[61456.]—**Caustic-soda Process.**—I have heard that this process of generating heat is used by some railway companies for heating foot-warmers. Will some reader kindly say if this is so, and explain in what way it is used, and whether the process is patented?—C. L. S.

[61457.]—**Orsat's Apparatus.**—I should be very much obliged to any reader of the "E. M." who could give me description, solutions required, and method of working this apparatus, more especially for the estimation of CO_2, O, and CO in chimney gases.—NICOMEN.

[61458.] — **Circular Saw Shaft.** — Having an amateur's lathe, 9½in. centre, I want to put an 18in. circular saw to work in it by power. I have got the saw; and the centre hole for the shaft is 1¼in. diam. What length shall I require the shaft to be, and which is the cheapest way to buy it—get a piece of rolled shafting or get one with a collar turned all ready?—WALTER PAYNE.

[61459.]—**Galvanometer.**—Will some of the readers of "ours" kindly give proper sizes and quantity of wire for coils of high and low-resistance galvanometer?—A. B. C.

[61460.]—**Stonemason's Shellac.** — Would any reader give a recipe for a good stonemason's shellac (white)?—S. H. W.

[61461.]—**Keeping Albumen.**—I have some eggs that have been kept in lime water, and through some of them getting cracked the others have been condemned for cooking. I want to save the whites for fining wine in a few months' time. If I whip the whites and let settle, what shall I do or add to it to keep the albumen good until I want it?—W.

[61462.]—**Legal.**—Will "Sperans" kindly answer the following? The parish wants to pave new streets with York paving, where ashphalte would answer the purpose. Have the owners of houses who are called upon to pay for this paving any voice in the matter? They also want to charge for paving front, side, and length of back garden, the said back garden bordering on another road. Is this legal?—NO SIG.

[61463.]—**Propulsion and Weight.**—Will somebody kindly help with the following? What is the proportion of power to weight required to propel weight? Is the proportion greater or less in water and air than on land? Which gives the best proportion—a man, horse, or loco. under ordinary conditions? Does a bird require a greater or less proportion than the best of these? As weight increases, must power be increased in same ratio? If not, how does it vary, and is it the same on land in water and in air? Do the best forms of electric accumulators with motor weigh less than loco. with paraphernalia to give same power?—W. J. G.

[61464.]—**Iodine.**—Will any subscriber kindly inform me the process seaweed is put through to obtain iodine? Also whether seaweed growing at the top or bottom of the sea gives the most iodine, and which gives the best quality? Any information on same will kindly oblige—JONA.

[61465.]—**Sinking Ropes.**—Will any reader kindly inform me the best type of rope to use for this purpose, and, if possible, give a formula for working out the strength it ought to be to carry certain weights? Size of pulleys, drums, &c., they would recommend for same, and any other information, will be gladly received.—J. O.

[61466.]—**Gold Gilding.**—Will someone kindly tell me how to put gold leaf on to rough models and wood?—J. F.

[61467.]—**Crayon Drawing.**—Will someone kindly inform me the best crayons and stumps to use for this work, and the best method of shading with same?—F. H.

[61468.]—**Brass Surface.**—Can any of your readers kindly tell me how the granulated surface is given to brass, such as you find in the centre of good old Queen Anne clock faces?—B. F.

[61469.]—**Lantern Slides.** — How are enamelled lantern slides made (not enamelled photographs)? They cost about 14s. per dozen, are coloured, and resemble pictures to be seen on dishes?—R. B.

[61470.]—**Legal.** — "Bulging out" of outer wall of house, a few feet under roof. Is freeholder liable (or leaseholder with usual repairing lease)? Causes decay, settlement, or vibration of railway trains. Also, which is liable in the case of leaking roof through decay of zinc covering?—BOB.

[61471.]—**Steam Heating.**—Having to fit up a large place with steam for heating the rooms, should be glad of any information respecting the same. (1) The arrangement of pipes? (2) How is the condensed water taken away? (3) How is the boiler supplied? Also if there is any work published on steam heating?—IGNORANT.

[61472.]—**Damp Houses.**—I shall be glad to know whether there is any simple and inexpensive apparatus whereby the dampness in a room may be detected and measured (a hygrometer is too costly). It seems quite useless to tell a landlord that his house is damp; he merely smiles at you, and does nothing. In these circumstances it would be of immense service to have a standard of dampness, so as to be able to say definitely how much dampness there is. The amount of misery, through various forms of illness, leading to consumption and death itself, inflicted on families is incalculable, and from constantly inhaling damp air.—HEALTH IS WEALTH.

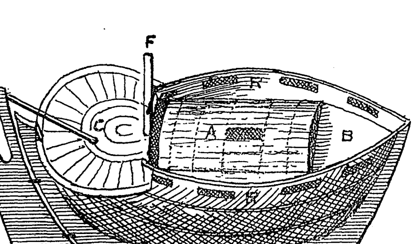
[61473.]—**Cell.**—TO E. CONRY.—In the number for Jan. 1st you were kind enough to say you would send particulars of a cell suitable for testing if I advertised my address. This I did in the edition published Jan. 8th. I fear the advt. has escaped your notice. I shall be quite willing to communicate with you before you send details, if desired, when I know your address.—FIX.

[61474.]—**Silver Cell.**—Querist has made a cell on the chloride-of-silver principle, which was intended to work a small coil. It was made up of a few old silver earrings, riveted together to form the silver plate. Upon this was melted chloride of silver. He put this and zinc plate into a test-tube about 3in. by 1in. Now here is the mystery: The excitant was to be zinc chloride, which he imagines is ordinary soldering fluid—viz., zinc dissolved in hydrochloric acid. This was done, but the cell gave no current at all. He then tried a solution of salammoniac, which worked it a bit; but not strong enough, and the zinc turned black. Should be glad if someone could put to rights the—CLEVER FELLOW.

[61475.]—**Automatic Blowpipe Apparatus.**—Can anyone inform me of an apparatus for blowing two blowpipes (¼in. holes)? It is worked with water. Hydraulic pressure can be got up to 500lb. by means of a treadle. This apparatus will work some time without treadling, and keep a continual blast.—TAL-CATO.

[61476.] — **Brass Foundry.** — (See Vol. XLIV. No. 1,135, page 362.) Would you be so kind as to tell me what would be the best stuff to fasten the brick of the furnace together? Would ordinary mortar do? Also, what would be the best fuel for the same, and the length from ashbox to chimney?—H. E. B.

[61477.]—**Name of Craft Wanted.**—Could anyone favour me with the name and nationality of the craft of which a rough sketch is inclosed, and the position and style



of the mast and spars, as I have a good model from the collection of the late Vice-Admiral Wilmot, K.C.B., but no description. A is the awning of rice-straw over hold; **B**, deck forward; C, platform or stern deck widely overhanging counter; R, bulwark, dark spaces being openings; F, upright with crutch at top for crest.—W. E. HALLS.

[61478.]—**Lenses.**—I have the drawings for a draw-telescope. Will some experienced person give me their advice as to lenses—i.e., who would be the maker to obtain them from? Am at a loss, there being so many makers said to be possessing merit.—B. B.

[61479.]—**Medical.**—Will one of our medical correspondents give me the best remedy for destroying the smell of smoke, &c., in mouth, which is very disagreeable when talking to anybody. The sweets sold for that purpose generally are so vulgar in perfume. Any advice will oblige—B. B.

[61480.]—**Medical.**—I have two bottles, one full of white quinine, the other steel drops. Are these to be used in combination, or separately? Please mention quantity. Also, for what purpose are they used, and their action on the system?—B. B.

[61481.]—**Newcastle and Carlisle Railway.**—Will Mr. Stretton kindly supply drawings of the "Comet" along with particulars of construction, for benefit of readers of "E. M."?—ROVER.

[61482.]—**To Loco. Correspondents.**—What is the difference in the heating powers of the firebox and the tubes in a loco. boiler? In Webb's compound passenger engine it is stated that the heating surface of the firebox is 84·84ft., and the tubes 908·87ft.; total, 993·71 sq. ft. What is the value of each in raising steam—i.e., how many sq. ft. of heating surface of the firebox are equal to 1H.P., and how many sq. ft. of heating surface of the tubes is equal to 1H.P.?—W. S.

[61483.]—**Heat of Water.**—Would "T. C., Bristol," or any other of your correspondents, kindly answer the following in plain figures? If a portion of cast-iron pipe, 12in. long, 4in. diam. (internal), and ¼in. thick, were heated to a temperature of 1050° Fahr., and it was suddenly filled with water at a temperature of 32° Fahr., to what temperature would the water be raised, supposing the whole of the heat was absorbed from the pipes? Specific heat of water nine times that of iron.—W. H.

[61484.]—**Metallic Hone.**—I have heard of a hone which is said to be remarkably efficacious for razors, made of some metallic substance, or mineral containing metal. It does not require oil, being soaked in water a few minutes before use. I believe it comes from Austria. If any of "ours" know of it, I shall be much obliged for the correct name, as I have failed to procure anything answering the description I have given.—D. G.

[61485.]—**Steel Spiral Springs.**—Will any kind reader tell me the greatest weight a steel spiral spring will force up a tube with ⅝in. bore? The spiral spring must go inside the above-sized bore, and the weight is to be attached to the end of the spiral spring; length of spiral spring when expanded, after throwing the weight as far as it will go, not to exceed 10in.—SPRING.

[61486.]—**Petroleum Gas Engine for Launch.** —As I intend getting a launch of galvanised steel built, about 40ft. long, would any subscriber be so good as give me some idea of proportions and lines of hull? Also a description of the engine and generating apparatus required to obtain a speed of not less than ten miles per hour?—GLASGOW.

[61487.]—**Gnomonic Projection.**—TO "F.R.A.S." —I wish to project a map of the British Isles, and the purpose I need it for requires that great circles on the globe be straight lines on the map. Kindly give me a hint how to draw the meridians and latitudes, supposing the plane of the map to touch the sphere in latitude 55° N. I can draw and divide central meridian and project the Pole and Equator.—K. E.

[61488.]—**Brass Tubes.**—I need a very large quantity of brass tubes, similar to those used as caps for pencil ends, ½in. long, half a line thick in the wall, half of them twenty-two lines in diam., the other half twenty-three lines. How are they to be drawn? Next I need to have them flattened in the top, as is done with small brass cartridges. How is this done? Lastly, I wish to have four turns of a spiral groove pressed into them, so that they will screw into one another when placed mouth to mouth. Can this be done? If any practical man thinks he could explain by letter, though not through "E. M.," he will be at no loss if he advertises his address.—A. E. S.

[61489.]—**Speeding Engine.** — A high-pressure engine, with cylinder 1ft. 6in. dia., 3ft. stroke, makes 80 revs. per min.; governors, known as Porter's, make 320 revs. The engine runs too fast: it wants to run 70 revs. per min. Would some correspondent kindly inform me what alterations to make in governor speed, &c.?—GOVERNOR.

[61490.]—**Acoustic Telephone Construction.**—Will some reader be kind enough to give me a sketch with size to work to, showing the construction of an acoustic telephone? Also if non-covered copper wire will answer better than galvanised wire? Also inform me if hard wood insulators, with indiarubber cores through, will answer for this telephone, as I wish to construct one to speak from my engine-room to boiler-house, a distance of 120 yards, overhead, to act as transmitter and receiver both, so as not to require any electric battery.—WORKHOUSE.

[61491.]—**Copper Castings.**—Would any of our numerous readers kindly tell me how to make copper castings from wood patterns? I have tried two or three places, but without success. Also, I have heard that there is a metal much resembling copper, which I think I could make do. Any information about either will be gladly received.—PERTH.

[61492.]—**Cells for Motor.**—Will some kind reader inform me how many pint bichromate cells would work a motor which I have, with Siemens armature, 3in. long, 1¼in. diam., fitted with 22 silk-covered wire; the field-magnets 4½in. by 4½in., fitted with 20 silk-covered wire?—COIL MAKER.

[61493.]—**To Change the Colour of Diamonds.** —Can any reader give particulars of the new chemical varnish which apparently has the effect of changing a yellow or off-colour diamond into a valuable white stone? It is stated that very few, except an experienced expert can detect this fraud (see the police report in the *Times* 3rd Jan., 1887).—SUBSCRIBER.

[61494.]—**Spurwheel Query.**—Will some reader kindly inform me the best method for constructing curves for the flanks and faces of teeth?—AMATEUR.

[61495.]—**Hot-Neck Grease.**—What is the composition of hot-neck grease, as used in rolling mills?—ANXIOUS.

[61496.]—**Wooden Pumps.**—I wish to know how the joints of the old-fashioned wooden pumps were made, and if there is any kind of tool turned by hand which will form the male and female cone, so as to be perfectly air and watertight when driven together. I wish to make water pipes, 2½in. bore, from a number of blown-down larch trees, and have shell auger used for boring beetling beams.—XXXIII.

[61497.]—"**Singing" Hammers.**—What are the best dimensions for a hammer which, when heated and placed on a block of wood, will give a sound of sufficient intensity

to be heard in any part of a large room? I have made some of various sizes without getting a satisfactory result. —S. H. W.

[61498.]—**Battery.**—On page 435, Jan. 14, 1887, there is a battery published by Mr. S. Bottone. Will he be kind enough to give me the length, breadth, and width of the carbons and zincs? Also, how many cells would it take to light a 10c.p. lamp?—J. H. WILSON.

[61499.]—**Storage.**—Have any of our electrical correspondents noticed, when discharging secondary batteries, that bubbles of gas rise between the plates, but stop if the discharging circuit be opened? If anyone has noticed it, I should like to have his help in the matter, or else be directed how to prevent it, as there must be a loss in capacity if the chemical energy of the battery be allowed to escape the way it appears to. In most textbooks we are told that a stranded conductor has a greater weight and carrying capacity and less resistance than the same number of wires unstranded. What is the explanation of this? I have looked through all the textbooks I possess for a description of the Thomson-Houston arc lamp, but have not be able to see any as yet. If anyone could give me a full description of its mode of working I should be much obliged. What is the best way to silver the back of an electric reading lamp, as I can't get the silvering to stick to the bulb?—IOTA.

[61500.]—**Lens.**—Will some reader kindly tell me the scope of a lens I purchased in London some time ago? I bought it for a half-plate; but I have only a quarter-plate camera, and I am contemplating purchasing a half-plate camera, if the lens will cover the plate. The image given is so small that I am in doubt about it. It is a double combination portrait lens, and glasses measure 1 9-16in., and on lens is "W.A. 4705." Who is likely to be the maker? —H. C. C. S.

[61501.]—**Battery Plates.**—Some time ago an idea was given in "Ours" that it would be an improvement in battery plates if they could be cast with mercury in due proportion. This I have been trying to do, but find the resulting plates so brittle as to render them useless. Can some of "ours" help me to remedy this?—H. C. C. S.

[61502.]—**Gilding Solution.**—I wish to make up half a gallon of gold solution, either by the chemical or battery process, the solution to contain about four pennyweights of gold. I have a one-gallon battery (Bunsen). Is this suitable for the job?—WOULD-BE GILDER.

A Telephone Palace.—There are probably no capitals in Europe where the telephonic system has been brought into more general use than is the case in Stockholm, nor can any other town vie with the Swedish capital as regards perfection of arrangements, &c. The plan adopted there, as in most Swedish towns, is a high degree of centralisation, which simplifies the service and saves time and money. There are in Stockholm two independent companies, of which the Almänna Telephone Company seems to be taking the wind out of the sails of the Bell Company. The former has at present some 3,600 subscribers, a large number for a moderately-sized town like Stockholm; and when its new building is completed there will only be two stations or centres, of which the new building will accommodate 3,100 subscribers. The new building referred to has, not without cause, been christened a telephonic palace, as, with one or two minor exceptions, the whole of the large edifice, from cellar to top, is given up to the various departments of the company. The most interesting feature is undoubtedly the large telephone room, its length being 110ft., with 30ft. breadth, which obtains its light partly through the ceiling and partly through windows. It is at present intended for 4,000 subscribers, but can be increased up to 7,000 subscribers. These 4,000 are divided among twenty tables, with 200 subscribers "proper" for each table, but according to the new and ingenious, although somewhat complicated, arrangements, all the other subscribers can "call on" each table, where the connection can then be established without communicating with other tables. There is also a special signalling system, which shows when a subscriber is engaged at another table. All this necessitates 16,000—and, should the service be extended to 7,000, 28,000—connections at each table. The number of connections increases in proportion to the square of the number of subscribers, so that 7,000 subscribers require 49 times as many connections as 1,000. The staff of clerks in this room is two at each table, and, as there is a double set, the total is 80 clerks. The wires in the telephone room are arranged in net fashion, and the wires within the room will have the fabulous aggregate length of 160 Swedish miles.—*Engineering.*

Steel from Horseshoes.—The following novel method of converting wrought iron into metal suitable for knife and sword blades is going the round of American technical papers:—"A shrewd Chinaman has hit upon an article of export from Germany which has thus far escaped the attention of the money-getting Teutons. It is neither more nor less than cast-off horseshoes, of which some Berlin firms are about to ship some 3,000 or 4,000 tons. The 'heathen Chinee' has found out that the wrought iron of which horseshoes are made, owing to the constant and even hammering on the pavement, together with the equine animal heat, gradually assumes the hardness of steel, combined with great malleability and elasticity, qualities which fit them more especially for the manufacture of knives and sword blades."

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

HOSPITAL SUBSCRIPTIONS.

THE suggestion made that hospital patients should benefit by the kindness of readers of the ENGLISH MECHANIC willing to defray the cost of a year's subscription for the benefit of any particular hospital, has been responded to by "D. G.," who sends us £1 2s. for two such subscriptions, which we have appropriated respectively to St. Bartholomew's and Guy's Hospitals; and by "R. S. T." (who first suggested the idea) who sends £1, which will be appropriated as far as it will go to the London and Charing-cross Hospitals.

The following are the initials, &c., of letters to hand up to Wednesday evening, Jan. 19, and unacknowledged elsewhere:—

W. GOYEN.—John Wood.—F. M. E.—A Fellow of the Royal Astronomical Society.—O. P. Scourfield.—C. A. W. —H. B. Fulton.—W. A. S. B.—F. A. M.—A. W. Stokes, F. C. S.—Amateur.—J. R.—M.M.I.Sc.S.—Edward Conry. —B. Payne.—W. M. S.—Young Ghazi.—Enquiry.—An Old Man and Upper Strapper.—Dusty Million.—Volt.— B. Boothroyd.—Dynamo.—T. C. C.—J. H.—Spectator.— Anxious Improver.—H. C.—W. A. W.

THEODORE ROUSSEL. (We are not aware that any prize has been offered for a geometrical solution of the problem of the trisection of angles.)—SAILOR. (Read the "Scientific Dialogues on the Tides" in Vol. XXXIX., and look through the indices of recent volumes for methods of calculating.)—A 12 YEARS' SUBSCRIBER. (Procure a catalogue from Messrs. Churchill, 11, New Burlington-street, W., and you will be able to suit yourself. You do not specify what anatomy you mean.)— WORKMAN. (Unwin's "Machine Design," Longmans; Campin's "Details of Machinery," Crosby Lockwood and Co.; but it would be advisable to ask the teacher of your class.)—J. C. (If you cannot refer to back volumes, procure a manual of "Practical Taxidermy," published by Mr. L. U. Gill, 170, Strand, W.C.)—BLOOMSBURY CONFECTIONER. (Mix any desired flavouring with the melted gelatine; pour out on slabs to cool, and cut up with a lozenge-machine. Perhaps, however, you mean gum lozenges.)—YOUNG TURNER. (Draw a line with a sharp point, and grind off to that.)—J. W. B. (Writing inks without galls are usually made of decoction of logwood and green copperas, or bichromate of potash.)— WATCH JOBBER. (Articles on watch-repairing have appeared in many back volumes—nearly all, in fact. Probably you mean the articles in Nos. 886, 888, 889, &c., through Vol. XXXV.)—F. J. A. (The brilliancy of the sun at noon is equal to that of about 600,000 full moons. Zöllner's determination is perhaps the best, and by two methods he found the light of the full moon to be one 618,000th that of the sun, and one 619,000th respectively.) —UNDER KEEPER. (Browning gun-barrels described several times; with full details in No. 1035, p. 456.)— ENGINE. (Equal parts rubbed together. 2. That is a defect of the horizontal form, which is generally remedied by carrying the rod through back cover.)— SHOPMAN. (Given many times. See pp. 463, 485, Vol. XXXVII., and the indices of back volumes.)—GLOVASKI. (You will probably find what you want in No. 1017, p. 61; but you had better send the wheels you want matched.)—NEW READER. (Perhaps the coil described in No. 1121 will suit you. 2. Galvanic belts can be made of pieces of zinc and copper separated by canvas, or with wires of zinc and copper wound on pieces of wood. 3. Leclanché described many times. The "new" Leclanché is made with patent agglomerate plates held to the carbon by rubber rings, and then immersed with a rod of zinc in a strong solution of sal-ammoniac.)—AN AMATEUR. (For details of nickel-plating, see Nos. 993, 994, 995. Not easy with a battery plant; but see the catalogue issued by the Electro-Metallurgical Co., Charlotte-street, Blackfriars, S.E. 2. You must not expect to do lacquering properly in half a dozen attempts.)— JOHN RIPLEY. (We have no knowledge of any cheap batteries except those described in our columns.)— WRITER. (Hall's type-writer was illustrated in No. 928. There is much about others in back volumes. 2. Of too little interest; for when made so few people can have any use for it.)—T. M. P. (It is early yet; perhaps it may be answered. Probably you would succeed in getting an electrotype by covering the mould with plumbago in fine powder, and connecting the battery wire to the plumbago. The actual process of electrotyping has been frequently described.)—C. E., M. E. (If the machine is not the subject of a patent, anyone can make it. What they do with it is quite another matter; but if your patent is infringed abroad, you have a remedy against the infringers, provided you have obtained a patent in the country where the invention is used.) — H. LANGSTON-CLIFFORD. (You will find answers to all your questions in the Act itself, and in the rules issued by the office. We have given full particulars, and the only amendments were specified in No. 1067. Ten months is the time now, and the specification can be seen as soon as its acceptance is advertised.)— INCUBATOR, B.O.T. (For incubators, see No. 1075, p. 181; No. 1007, p. 425; No. 1009, p. 471; and No. 935, p. 562.)—W. H. H. (It depends on what you mean by "enamelling." See p. 243, last volume, and the indices generally.)—MECHANIC. (Certainly there is solid silver and gold; but articles of jewellery are generally made hollow or with a filling, and in the case of gold are rarely made with pure metal. 2. Not more dangerous than at other times; but it depends on the nature of the enamel, or china, as you call it.)—H. CHEWNELL. (You must say more definitely what is meant by "ancient weather glasses"; but you will find several old-fashioned forms described in back volumes.)— FLOWER-POT. (Why make holes in them? It is usual to stand the ordinary pots inside. A sharp drill kept wet will go through, or you can use a bit of copper tube and emery with oil. Notch edge of tube slightly, and keep up a steady pressure while revolving the drill.)— J. M. (No doubt there is some affinity; but at present very little is definitely known about the matter. Why should they be pressed flat when the silex is deposited from liquid?)—SKATER. (A patent costs £4, £1 being paid on application and £3 with the complete specification which need not be lodged until 10 months after the application. Procure one of the handbooks advertised by patent agents in our columns.)—IVORY. (Ivory is bleached by exposing it under glass to the action of the sun. The bleachers use frames which resemble those to be seen in gardens for protecting or raising plants. It must not be exposed to the sun without the protection of glass.)—GIDEON. (The obvious remedy is to hang them up somewhere to dry. If you mean they are already "dry," the preparation with which they have been dressed extracts moisture from the air.)—A CABINET-MAKER. (The photo-zincotype process is cheapest. Make drawings in firm lines twice the size required, and any of those firms who make "process" blocks will supply you with what you want.)—MONO. (Several recipes in back numbers; but whether they will suit your purpose can be determined only by experiment.)—A. C. (Use silk-covered wire for all coilwork. You will find all necessary particulars in even recent numbers.)—C. S. (The paint is laid on with an oil varnish; probably a clear spirit varnish over that would produced the effect desired.)—A COUNTRY COUSIN. (There are several recipes in back volumes. All "wines" of the kind "go bad" unless they are "fortified" with spirit.)—AMATEUR CARPENTER. (Perhaps you would find what you want in our back volumes; but Charles's "Practical Cabinet-Maker," Spon, and Tredgold's "Elementary Principles of Carpentry," Crosby Lockwood and Co., may possibly meet your desires.)—SOMERSET LAD. (The question is too wide or too vague. There is no formula that will suit all conditions. The simple rule is that the air-vessel should be three or four times the capacity of the pumpstroke for ordinary work; but for high pressure, quick-working pumps seven or eight times.)—A. SMITH. (The question should have indicated what is meant by enamelling. See p. 243 last volume, or No. 952 for a general article on enamelling.)—A. B. C. (See indices. There is no book on its construction that we know of. The other questions are simply advertisements, which should appear in the Wanted Column.)—PUZZLED. (The rod can actuate a lever carrying the hammer, or work a jack with a spring hammer, as in the well-known tablebells.)—SANITAS. (We cannot tell you how to get admission to the Plumbers' Company. They have, we believe, some scheme on hand for the registration of workmen and masters as efficient plumbers; but the number registered yet is very few comparatively. We should think a certificate of examination by the Sanitary Institute of Great Britain would be much more useful to you.)

Engineers and Stokers.—The work in an Atlantic liner is difficult, arduous, and unrelenting. It demands energy, presence of mind, and technical skill of a high order. The bare enumeration of these qualifications is a guarantee that in a British ship no special preference will be given to foreigners. The engineers are mostly Scotch, the stokers Irish. The qualities most required in the stokehole are a dogged resolution to face discomfort and a sturdy frame. The stoker is begrimed with coal dust. He has to endure an atmosphere which sometimes rises to a temperature of 130°. In this intense heat he has to shovel every day five tons of coal into the furnaces, and to keep the fires clear and bright by constant raking and by the periodical removal of ashes. Upon none have the burdens of the mechanical development of our age fallen more heavily than upon the men who undertake the duties of firemen in an Atlantic liner. Who can refuse to follow Mr. Ruskin in his admiration for the life of a sailor, and the beauty of the swelling canvas which it is his business to handle, or withhold his sympathy from those who are engaged in the wretched labours of the stokehole? It has often been proposed to feed furnaces mechanically. The method would obviate the necessity of employing men in one of the most distressful forms of manual labour. —*Lord Brassey, in the Nineteenth Century.*

NOTES ON THE CHURCH ORGAN.
IV.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

NEXT in importance to the foundation stops, and their harmonic companions, commented on in the preceding article, come the *Doubles*, or manual registers of 16ft. pitch. There can be no question as to their utility and importance in a Church Organ. Considering the instrument in its more important function—that of accompaniment to a number of voices singing in harmony—it will be observed that the unisons, combined with the octave and harmonic stops, sustain the Trebles in a perfectly satisfactory manner; but that the Tenors and Basses are by no means adequately supported and enriched. To give them the support required a *Double Diapason* or some telling 16ft. register is absolutely necessary. Hence the importance of having such a stop in every Church Organ of any pretensions. In addition to the necessity of having a *Double* for ordinary accompanimental music, such a step is of the greatest value in imparting fulness and dignity, unattainable by any multiplication of unison registers. Dr. Hopkins, who has carefully studied this important question, remarks:—"If a chord be played in the Treble part of the Great organ of an instrument placed in a large building, and not having any stops lower in pitch than the unison, there will be perceived a certain *smallness* of effect, which makes it evident that, although the Treble may possess sufficient brightness and intensity, perhaps even amounting to shrillness, yet it lacks the amount of fulness and volume necessary to produce an ample and dignified tone. This arises from the fact of even the Unison Pipes in the Treble being comparatively acute in their sound; and, therefore, in the very nature of things, unpossessed of stately impressiveness. It thus becomes obvious that the harmonic-corroborating series of Stops alone do not present *all* the resources necessary to form a satisfactory organ. Something that is essential appears to be wanting; and a fresh element is felt to be necessary to supply that absent property. The property wanting is *gravity*, which possesses a character peculiar to itself, and for the absence of which no amount of *intensity* in the other sounds will compensate. Of the travelling and filling-up character of grave sounds we have already spoken; and of the fact itself, a sufficient illustration is given in the circumstance of a chant sung by twenty tenor and bass voices, in unison, pervading a building more completely than if sung by thrice the number of trebles. Again, the deep tone of a Pedal Diapason will travel through a building more entirely than a double chord of six or seven notes played on the Manual Diapasons from middle c^1 upwards. Its sound will certainly not be nearly so well defined; but it will be of a more pervading character. The want felt, and above specified, however, is not a *substitute* for the harmonic sounds, but a new element, which, *added* to them, shall render the general tone larger and more ample. It is worth mentioning that this want was so much felt, nearly three centuries and a half ago, abroad, that means were, even at that period, taken to supply the deficiency. It was about the year 1508, that a Covered Stop of 16ft. size of tone was invented in Holland; and which, to some extent, imparted the necessary, deep, resonant, *humming* effect to the other Stops, and was hence expressly called *Bourdon*—a name that means a hum or drone; and which Stop has never ceased to be highly valued abroad to this day."

From what is above written, the reader can hardly fail to realise the great importance of a stop of 16ft. pitch on the manuals; and it now remains for consideration what description of stop should be introduced in organs of different sizes; and at what point, with reference to the contents of the organ, the *Double* becomes advisable if not imperative. The latter question may conveniently be taken first. So soon as sufficient unison, octave, and harmonic tone is provided to accompany, in a fairly effective manner, the voices of the choir and congregation, then the *Double* should be added to the manuals in preference to any further multiplication of unison stops of an orchestral or fancy character. Once the manual departments furnish the true elements required to support, equally, *all* the voices in four-part harmony, then and then only may imitative and fancy stops be contemplated, with the view of further enriching the general tone, and securing the means of imparting variety of colouring to the lighter accompaniments, and to the incidental music of the services. Speaking roughly, and merely by way of general guidance, I should say that every Church Organ, which has an independent Pedal organ, should have a *Double* added to the manual department, even when it comprises only ten stops in all. Turning to Roosevelt's Specifications, I find my opinion supported. In his Church Organ, Style Thirteen, the single manual department comprises nine speaking stops, one of which is a *Bourdon*, 16ft. tone, throughout. Every Church Organ from this size upwards to twenty speaking stops should have one manual *Double*; and when it reaches that number it should have a stop of 16ft. pitch on each manual, one of which should be an open register—*Double Open Diapason*, *Double Dulciana*, or *Contra Gamba*. The present almost universal practice of having only one covered stop of 16ft. tone, usually placed in the Swell department, even in organs of considerable size, I unhesitatingly condemn, and it unfortunately happens that such instruments have lamentably deficient Pedal departments, making matters still worse.

Now, with reference to the description of 16ft. toned stops most suitable for Church Organs of different sizes, and for insertion in their separate manual departments, the following brief hints may be worthy of consideration:—When funds and space are both limited, and the church is of small dimensions, a *Lieblich Gedackt*, which neither occupies much room nor costs a large sum, will be sufficient to give the required support to the Bass and Tenor voices, and to impart dignity and gravity to the general organ tone. If the organ is a two-manualled instrument, of about 12 or 15 stops, with the full complement of couplers, the *Double* should be placed in the Swell department. In somewhat larger instruments a *Bourdon* of medium scale should be introduced in the Swell department, and where circumstances permit, a soft stop of 16ft. pitch should be added to the Great department. This may be an open metal stop from Tenor C, the bass octave being carried down in stopped wood pipes. When a Church Organ comprises from 25 to 30 stops, in addition to a *Bourdon* in the Swell, there certainly should be a full-scaled *Double Dulciana* or small *Contra Gamba* throughout in the Great. In a still larger instrument, a medium-scaled *Double Open Diapason*, voiced to a full round tone, becomes a necessity in the Great department, especially if the organ is placed in a spacious building, and has to support a large and properly balanced choir. I need scarcely point out that the Swell to Great sub-octave coupler gives the organist ready means of adding several strengths and varieties of 16ft. tone, down to Tenor C, on the Great clavier; and, further, a soft 32ft. tone to the same note when the *Bourdon* in the Swell is drawn. The utility of this valuable coupler is thus made apparent. Few Church Organs have a stop of 32ft. pitch on the manuals. I may mention two instances in this country — the organ in the Parish Church, Leeds, the Great department of which has a *Sub-Bourdon* of metal and wood, 32ft. tone from Tenor C; and the organ in the Parish Church, Doncaster, where a *Sub-Bourdon*, from Tenor C, occupies a similar position. The Great department of the latter instrument has three stops of 16ft. pitch, the Swell two, and the Choir, Solo, and Echo one each. The great importance of the manual *Doubles* is here fully realised.

On the subject of other flue stops desirable in the Church Organ, it is unnecessary to dwell at length; for, as I have already said if the foundation-work is adequately represented in all departments, the Church Organ, properly so-called, will be safe. Up to the present point I have, with the single exception of the manual *Double*, spoken of open metal stops only—the stops which form the vertebræ of the tonal structure of the organ —now I may direct attention to another class of stops which is only of secondary importance to the open foundation stops. I allude to the stopped or covered registers, known by the names, *Stopped Diapason*, *Lieblich-Gedackt*, *Doppel-Flöte*, &c. These stops, when of proper scales and carefully voiced, produce tones of good mixing and filling-up character, imparting to the foundation tones singular roundness and increased volume. This is caused by the entire dissimilarity of their sounds, and, accordingly, the total absence of that sympathy which is destructive of volume and tonal effect in combination. Of the stops just named, the *Doppel-Flöte*, or double-mouthed flute, is by far the best for the Great department, where a great volume of quiet pervading tone is desirable. The *Stopped Diapason* and *Lieblich-Gedackt*, are suitable for the Swell and Choir departments. It is much to be regretted that the *Doppel-Flöte* is practically unknown in England; and that none of our builders seem disposed to undertake its manufacture. The stupid notion that the characteristic tones of such stops can be imitated by ordinary metal pipes has done and will continue to do much to retard the proper use of wood stops. I unhesitatingly affirm that the peculiarly full and filling-up qualities of the true *Doppel-Flöte* cannot be obtained from a single-mouthed metal stop. The only modern builder who recognises the full value of the *Doppel-Flöte* is Mr. Hilborne L. Roosevelt, of New York. He never schemes a Great department of any importance without including a *Doppel-Flöte*; and in this he gives one of the many proofs of his artistic knowledge and judgment. The stop requires great care in its manufacture, and is troublesome and tedious to voice; these facts, I believe, are sufficient to keep it out of the generality of our English workshops for ever. Again, alas for art! Next to the true organ tone in importance is that known as flute tone, such as is produced by the covered stops just alluded to and by numerous other registers of both wood and metal. Flute tone, when of a refined quality, is extremely valuable for vocal accompaniment, and in imparting that solid variety which is desirable, without impoverishing the general effect. This tone must, however, in all cases, be kept strictly subordinate to the true organ tone.

Stops producing tones which imitate, more or less closely, those characteristic of the family of orchestral stringed instruments, although of much less value in a Church Organ than those previously alluded to, may,

with advantage, be introduced in the Swell departments of larger-sized instruments. They enter into combination with the flute-toned stops, producing bright effects and materially enriching the resources of the organ, especially for incidental music. The string-toned stops should, like all the other registers introduced in the Church Organ, be characterised by richness and body of tone, rather than by that pungency, which, in too many modern examples, approaches a scream-ing or hissing quality.

In such a hasty and necssarily imperfect sketch as the present, I may omit any direct allusion, in detail, to those organ stops which may justly be designated "fancy stops." Such stops may be desirable in large, many-manualled instruments, but are of little value in small Church Organs, where, it is more than probable, their presence is secured at the sacrifice of registers of infinitely greater value and importance. The craze which obtains amongst "sucking organists" and a large section of the organ-loving public for ear-tickling stops is just as absurd as it is pernicious to true Church Organ building. I may, therefore, conclude this part of my essay with a few remarks on the reed stops most suitable for small and medium-sized Church Organs; and with a hasty glance at desirable stops for the Pedal department.

When a Church Organ has been properly schemed as regards its foundation-work and flue-work generally, it requires but little aid from reed-work. Its presence is, however, very desirable, for it imparts what may be called a golden glory to the already richly coloured embroidery of sounds. Dr. Hopkins has tersely and aptly described the offices of all the great classes of organ stops in the following words:—"Open Stops of the Diapason kind, alone, would produce rather a cutting tone; an organ entirely of Covered stops would sound weak and muffled; while one composed entirely of Reeds would be too strong and penetrating. The four great classes of organ Stops—Open, Covered, Flute, and Reed—are, in fact, to a great extent dependent on each other for the production of the most satisfactory result. The Covered Stops impart a quiet solidity to the Open Stops; the Open Stops bestow roundness and firmness on the Covered Stops; the Flute Stops give variety and increased character to the soft combinations; while the Reed Stops impart to the full organ stateliness and splendour, and in return receive fulness and brightness from the Open series of Stops."

The most important of all the manual reed stops is the *Trumpet*. When this is properly scaled and skilfully voiced, it adds a highly desirable "stateliness and splendour" to the full organ tone. The octave of this stop, called the *Clarion*, is a useful adjunct, when the instrument reaches sufficient size to demand a very pronounced octave tone. Next to the *Trumpet*, in general usefulness, comes the *Oboe*, a pleasant, soft-toned unison reed. In very small organs, placed in churches of small dimensions, in which a *Trumpet* would prove somewhat overpowering, the *Oboe* is the most appropriate register.

In order of interest and importance now comes the *Clarinet*, a unison reed stop of imitative and pleasing quality, imparting an agreeable variety to the softer combinations, and a certain richness and colouring to all combinations in which it may enter. This stop is almost invariably placed to great disadvantage in ordinary Church Organs in this country; for, although of all organ stops it is *the one* which most loudly demands means of expression, it is almost universally relegated to a department which, in English Church Organs, is never inclosed in a swell-box. For those instruments of medium size, in which more than the above named unison reed stops may be considered desirable, either the so-called *Horn* or *Cornopean* (usually an indifferent *Trumpet*) may be adopted. As in all my foregoing Notes I have been directing attention to Church Organs of generally useful size and character, rather than to those huge instruments which have of late years been placed in churches, and which only too often remain as reproaches against all persons concerned in their erection, it is unnecessary for me to speak of the several reed stops, high-pressure and otherwise, which only find their legitimate place in concert-room instruments. Where space will permit, and when the organ stands in a large church, it may be found desirable to insert a reed stop of 16ft. tone in a manual department. The stop may either be a soft *Double Trumpet*, or, what is usually preferable, a *Contra Fagotto* or *Double Bassoon*. The *Vox Humana*, of which so many vile examples exist in English Church Organs, occupying the place of really important and badly wanted stops, is a useless and undesirable register. It must be classed amongst the ear-ticklers I have already spoken of. It is of no use in accompaniment, unless it is to show what a miserable travesty it is of the *human voice*.

I may conclude this article with a very brief allusion to the more desirable stops strictly belonging to the Pedal department of the Church Organ. In the proper appointment of this very important department two impediments almost invariably arise—namely, circumscribed space and insufficient funds. An adequate Pedal organ is, of necessity, a costly and a cumbersome affair; but if a perfect or even a useful instrument is aimed at, an adequate Pedal department must be provided. It is out of all reason to expect the booming, master-of-all-work *Open Diapason*, or the tubby *Bourdon* usually met with in Church Organs, to furnish a true or satisfactory bass for the whole or indeed any considerable portion of the manual departments. It must be recognised, once for all, that the true office of the Pedal stops is to carry down and to furnish correct basses for the foundation and other important stops in the manual organs, and unless they do so the Pedal organ is a fraud. I shall have more to say on this topic when I come to the consideration of the Pedal organ in detail.

The unison pitch of the Pedal Organ is 16ft., and the most useful registers of this pitch are the *Open Diapason*, *Violone*, *Dulciana*, *Bourdon*, and *Lieblich-Gedackt*. In all possible cases an *Open Diapason* should be introduced, providing the foundation tone. In scale, this stop (in wood) need never exceed 12in. by 14in., inside, at the C C C pipe; while, in general, 10in. by 12in. will be ample. The *Violone* may either be metal or wood, with open pipes of small scale, voiced to imitate the tones of the orchestral Double Bass. This, when of soft and refined quality, is an invaluable stop in accompanimental music. The *Dulciana* is a very softly-voiced, open metal stop of smaller scale than the *Violone*, yielding pure organ tones, admirably adapted for the bass of the softest accompaniments. The *Bourdon*, a much-abused and much over-used stop—the delight of the cheap organ builder—is a valuable register in its place in the tonal scheme of a Pedal organ; but, except in the smallest Church instruments, should never be depended on for the principal 16ft. tone in the department. The *Lieblich-Gedackt*, when carefully voiced and copiously winded is a most valuable register. It is of very small scale, and accordingly, occupies little floor space. It is a serviceable stop in conjunction with an *Open Diapason*, and should be adopted in preference to the usual large-scaled *Bourdon*.

Every Pedal department should have an *Octave* (8ft. tone) stop. In very small instruments this may be borrowed from a 16ft. stop, by means of an Octave coupler and an upper octave of pipes: but in all possible cases, an independent *Octave* should be inserted, either in the form of a flute-toned or string-toned stop of softer intonation than the chief unison.

In instruments of medium size, a *Quint* (10⅔ft.) may be introduced. When drawn with a stop of 16ft., it produces, though faintly, an impression, on the ear, of the 32ft. tone. In larger organs, instead of the *Quint*, I strongly recommend the adoption of the *Contra-Bourdon* of 32ft. tone. When well made and favourably located this stop speaks in a very satisfactory manner.

Next in importance to the Pedal organ registers already noticed, come reed stops of 16ft. tone. Of these, the *Double Bassoon* and *Trombone* are the most useful. An octave reed, in the shape of a *Trumpet* (8ft.) may be added when the Pedal department approaches completeness.

It is, of course, desirable to introduce an open stop of 32ft. when space and funds permit; although it is hardly necessary to do so unless a stop of 16ft. pitch appears in each of the manual departments. Then follow, in complete Pedal organs, the mutation and harmonic-corroborating series of stops. I shall have more to say on this subject in my concluding article, where I shall also direct attention to Mr. Thomas Casson's new system of organ building, which practically overcomes the great difficulty which has hitherto obtained in providing an adequate Pedal organ for small and medium-sized instruments, and which may, to a large extent, be adopted with advantage in all Church Organs, whatever their size may be.

(To be Continued.)

ASTRONOMICAL NOTES FOR FEBRUARY, 1887.

The method of finding the Sidereal Time of Local Mean Noon will be found on p. 382.

Destitute of spots for many days together, and altogether in a quiescent state, the Sun is in a particularly uninteresting phase for the observer.

There will be an Annular Eclipse of the Sun on February 22nd; but as it will only be visible in the Southern Hemisphere, no further reference is needed to it here.

The Moon

Enters her First Quarter at 8h. 26·8m. a.m. on the 1st, and is Full at 10h. 14·3m. a.m. on the 8th. She will enter her Last Quarter at 1h. 32m. in the early morning of the 15th, and be New at 9h. 40·2m. on the night of the 22nd.

An illustrated explanation of this table will be found on p. 384.

6 a.m. on the 6th; with Venus at midnight on the 9th; with Jupiter at noon on the 13th; with both Mercury and Mars at 3 a.m. on the 24th; and with Venus at 5 o'clock on the same evening.

Mercury

Is an Evening Star throughout the month, and towards the end of it may be caught by the naked eye after sunset glittering over a point of the horizon a little to the South of West. Although he Souths after *Mean* Noon on February 1st, he will be in superior conjunction with the Sun at 6 p.m. on the 6th.

Mercury.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	20 53·4	19 39·9	0 0·9 p.m.
6	21 21·5	17 37·8	0 16·2 „
11	21 56·6	14 31·7	0 31·6 „
16	22 31·3	10 50·7	0 46·5 „
21	23 4·8	6 42·7	1 0·3 „
26	23 35·5	2 25·6	1 11·2 „

Beginning thus in Capricornus, the path of Mercury extends right across Aquarius, and terminates in Pisces. It is free from any conspicuous stars. At 4 p.m. on the 23rd Mercury will be in conjunction with Mars.

Venus,

Like Mercury, is an Evening Star, but is only slightly gibbous, and her angular diameter increases quite imperceptibly from only 10·2″ to 10·3″. Also like Mercury, she may be caught after sunset towards the end of February. She is a very uninteresting object in the telescope at present.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	21 58·2	13 59·9	1 12·5 p.m.
6	22 22·2	11 47·0	1 16·8 „
11	22 45·8	9 26·3	1 20·6 „
16	23 9·0	6 59·5	1 24·1 „
21	23 31·8	4 28·1	1 27·2 „
26	23 54·5	1 53·6	1 30·2 „

The path indicated by the above ephemeris begins in Aquarius, and terminates in Pisces. It is in a comparatively blank region of the sky.

Mars,

For all purposes of the observer, is invisible.

Jupiter

Is a Morning Star, and is in anything but a favourable position for the observer. As, however, he rises between 10 and 11 p.m. at the end of February, we resume our ephemeris of him. His angular equatorial diameter, which is 35″ on the 1st, increases to 38″ by the 28th.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	14 14·0	12 4·5	5 29·5 a.m.
6	14 15·0	12 8·4	5 10·9 „
11	14 15·7	12 10·8	4 51·9 „
16	14 16·0	12 11·7	4 32·6 „
21	14 16·1	12 11·0	4 13·1 „
26	14 15·9	12 8·8	3 53·1 „

So that Jupiter describes a very short arc (partly returning on itself) between κ and λ Virginis.

Saturn

Is still visible all night long, and from his considerable elevation when near the meridian continues to be excellently placed for the observer. As we observed last month, the South Pole of the planet now hides Cassini's division in the ring, and extends, in fact, quite up to, if not just beyond, the southern edge of ring A. The equatorial diameter of the planet, which is 18·3″ on the 1st, diminishes, absolutely insensibly, to 17·6″ by the end of the month.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	7 14·6	22 12·5	10 27·4 p.m.
6	7 13·2	22 15·6	10 6·3 „
11	7 11·9	22 18·4	9 45·4 „
16	7 10·7	22 21·0	9 24·6 „
21	7 9·8	22 23·2	9 3·9 „
26	7 8·9	22 25·1	8 43·4 „

The short retrograde path thus described by Saturn, starts from a point so close to δ Geminorum, that for the first four nights in February the planet and the star will be in the same telescopic field of view. Towards the end of the month Saturn will be a little to the west of this star.

Uranus

Will scarcely come into an available position for the ordinary amateur observer until next month.

Neptune

Is now approaching the West, and should be looked for as nearly about the time of his meridian passage as may be convenient. His height above the horizon at this time renders his position very favourable for telescopic observation.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 32·4	17 21·7	6 45·8 a.m.
6	3 32·4	17 22·0	6 26·2 „
11	3 32·5	17 22·5	6 6·6 „
16	3 32·6	17 23·2	5 47·0 „
21	3 32·8	17 24·1	5 27·5 „
26	3 33·0	17 25·2	5 8·1 „

So that Neptune remains sensibly in the same part of that blank region of the sky rather less than 6½° to the South (and just to the West) of the Pleiades, which he has occupied during the whole of his recent apparition.

Shooting Stars

May be looked for with the greatest chance of success on the nights of the 10th and the 19th.

Greenwich Mean Time of Southing of Fifteen of the Principal Fixed Stars on the Night of February 1st, 1887.

Star.	Souths. h. m. s.
α Ceti	6 9 51·12 p.m.
α Persei...	6 29 41·49 „
γ[1] Eridani	7 6 5·22 „
Aldebaran	7 42 40·29 „
Capella...	8 21 28·70 „
Rigel	8 22 14·17 „
α Leporis	8 40 49·57 „
α Orionis	9 2 4·59 „
Sirius	9 53 3·29 „
Castor	10 40 8·97 „
Procyon	10 46 7·68 „
Pollux	10 51 7·78 „
β Cancri	11 23 1·73 „
ι Ursæ Majoris	12 4 0·02 „
α Hydræ	12 34 28·92 „

The Method of finding the Greenwich Mean Time of Southing of either of the Stars in the above List for any other night in February, as also that of determining the Local instant of its Transit at any other Station, will be found on p. 384.

PAICE'S BORING BIT.

IN the annexed illustrations are shown two forms of boring bit recently patented by Mr. A. Paice, of Ryde, Isle of Wight, whose object is to so construct boring bits that the hole or aperture made by them shall be perfectly level at bottom, and without the indentation formed by a point or screw in the centre as with the boring bit of ordinary construction; and also that the side or circumference of the hole or aperture shall be smooth and free from cutter marks.

Fig. 1 is an elevation of the boring bit, provided with flat cutter; Fig. 2 shows the lower end of bit provided with a spiral cutter, and with an adjustable stop; and Fig. 3 is a section through line A A, Fig. 1. The improved boring bit is made of steel or other suitable metal in the form of a hollow tube F, with a cutter, or cutters, G, extending from the outside to the centre. The cutters G are either fixed immovably to the inside of tube F, or are formed so as to run in dovetailed or other suitably-shaped slots, as best seen at Fig. 3. In the case of the cutter running loose in slots, the upper part is extended in the form of a small rod B which passes up the centre of the tube F; and tapped on the end of this rod B is a small thumbscrew C. The waste wood, when the bit is used, passes up the tube F, and outwards through openings H. The upper end of the tube F is closed in solid, and has a hole provided for the upper end of rod B to work in. It is also formed with two projections D (or it may be one projection extending right across) below the thumbscrew C. The lower end of the tube F is formed so as to receive the cutter, and is sharpened on the inside, and the bit is also provided with an adjustable stop E (Fig. 2). In the case of small-sized bits there may be only one cutter extending to the centre of tube instead of right across. When it is desired to use the bit the thumbscrew C is turned so as to withdraw the cutter from the end of tube F, then when the bit is sufficiently started the thumbscrew C is turned back, and so causes the cutting edge to project to the required distance from the end of tube F, and, consequently, if properly sharpened, the tool leaves the bottom

FIG 1

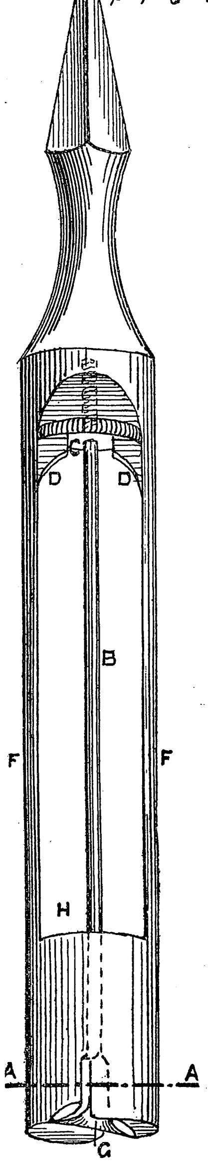

FIG 2

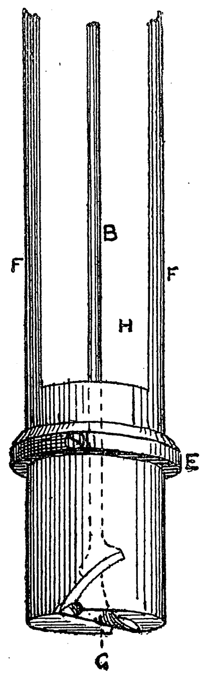

FIG. 3

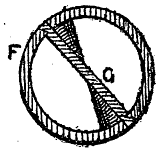


of the hole perfectly flat, and with no indentations. When it is desired to apply this invention to augers, the patentee fixes the cutter so as to project the required distance from the end of the tube, and the tube may remain intact with the opening at the top for the waste wood to pass outwards.

THE ELECTRO-DEPOSITION OF ALUMINIUM.

IN his "Electricity," &c., Mr. Sprague says, referring to aluminium, "the depositing of this metal would be a process of great value in the arts," and then proceeds to state that several processes have been published, but none is of any practical value. Mr. Sprague also says that all the solutions he tried —acid, neutral, and alkaline—decomposed and gave off gas, but refused to deposit metal. He believes, however, that aluminium may be more readily deposited in alloy with other metals. Sainte-Claire Deville thought it impossible to obtain aluminium from aqueous liquids by electrolysis, though the experiment of Bunsen in the production of barium did much to shake his conviction. Like Mr. Sprague, Deville failed to obtain good results, although he tried all the processes known; and yet it is stated that aluminium can be deposited. Thus it is said that Corbelli, of Florence, deposits the metal by electrolysing a mixture of rock alum and the chloride of calcium or sodium, the anode being formed of iron wire covered with insulating material, and dipping into mercury placed at the bottom of the solution, and the cathode of zinc immersed in the solution. The aluminium is said to deposit upon the zinc. In 1854 and 1855, Thomas and Tilley took out patents for depositing aluminium from a solution of calcined alum in aqueous cyanide of potassium. The patents included the deposition of aluminium alloys. Amongst other statements made, is one by Mr. J. B. Thompson, who asserted that he had been depositing aluminium on iron, steel, &c., at a temperature of 500° Fahr.; but C. Winckler stated soon afterwards that plating with aluminium cannot be effected by electro-deposition. Jeancson's is an American process, a double salt of aluminium and potassium being employed at a specific gravity of 1·161, using three Bunsen cells, and a temperature of 140° Fahr. M. Bertrand asserted that he had deposited aluminium on copper from a solution of the double chloride of aluminium and ammonium; and Goze's process is the simplest of all, for he is said to have obtained a deposit from a dilute solution of the chloride, by placing in it a porous pot containing dilute sulphuric acid and amalgamated zinc, the latter connected to a copper plate immersed in the chloride. Another method of depositing metallic aluminium electrolytically has been recently patented in this country on behalf of Count Rudolphe de Montgelas, of Philadelphia, Pennsylvania.

In this process, the aluminium is first obtained in combination with either lead, zinc, or tin, according as the oxide of either metal is added to the electrolytic liquid. The lead, zinc, or tin is then separated out in any well known way, and the metallic aluminium is thus obtained. The current of electricity employed should be of low electromotive force. As the invention may be conveniently carried into effect in the single decomposition cell, it is described in that connection. The cell may consist of an outer vessel, and an inner porous vessel. In the porous vessel is an element of amalgamated zinc, and an exciting liquid consisting of dilute sulphuric acid. In the outer vessel is an element preferably of brass or copper. The electrolytic liquid, which is placed in the outer vessel, is prepared as follows:— Alumina is treated with hydrochloric acid, and hydrochlorate of aluminium in fluid form is thus obtained. The specific gravity of the liquid is about 1·3 and density 35° B. As above stated, it is placed in the outer vessel of the cell and circuit is closed between the elements. As iron is usually present in the liquid, this metal is first electrolytically deposited upon the brass or copper plate, as a cathode. The operation is to be watched until the deposition of iron ceases and that of aluminium begins, which is apparent by a perceptible change of colour in the deposit. When this occurs, the iron has been removed. The operation is then arrested and the liquid decanted into the outer vessel of another cell similarly arranged to that already described. To the liquid is then added about fifty per cent. by weight, of either lead oxide, tin oxide, or zinc oxide. The terminals of the cell are connected and electro decomposition of the liquid results in the deposition of aluminium and the metal of the added oxide at the cathode. When this deposition is completed, the deposit is removed from the cell, and the aluminium is separated from its accompanying metal in any suitable way known to metallurgists and chemists. It will be observed that the function of the first mentioned cell is simply to remove the iron by electro-deposition. The invention is not limited to this particular mode of removing the iron, because other methods of accomplishing a like result may be adopted. So also the invention is not limited to the deposition of the aluminium in the single decomposition cell. Thus a galvanic bath may be made containing the aforesaid electrolytic liquid, in which electrodes may be placed, and to the electrodes the current—always of low strength—may be conducted from a dynamo or any other suitable source of electricity.

It will be observed from the above that so

far as plating with aluminium is concerned, we are as far off as ever, and it may be doubted whether any process for obtaining the aluminium will compete with the Cowles electrical furnace.

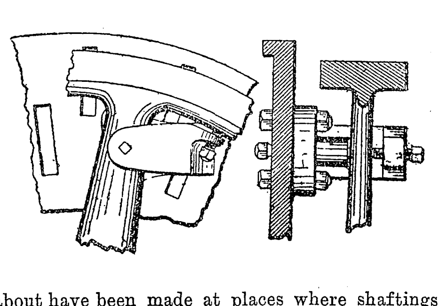
SIR W. THOMSON ON THE ORIGIN AND DURATION OF THE SUN'S HEAT.

IN the course of his lecture at the Royal Institution last week, on the "probable origin, total amount, and possible duration of the sun's heat," Sir W. Thomson said that for several thousand years the sun had been giving heat and light to the earth as at present, possibly with some considerable fluctuations. The natural history of plants and animals within the time of human history abounded with evidence that there had been no exceedingly great change in the intensity of the sun's heat and light during the last 3,000 years; but there might nevertheless have been changes of quite as much as 5 or 6 per cent. But as for the mere age of the sun, we had proof of something vastly more than 3,000 years in geological history, with its irresistible evidence of continuity of life on the earth probably for millions of years past. The sun, then, had been doing work at the rate of 476,000 millions of millions of millions horse-power, and at possibly more than that rate for a few million years. How this was to be explained was a problem which natural philosophy could not evade. The explanation which possessed the highest degree of scientific probability that could be assigned to any assumption regarding actions of prehistoric times was Helmholtz's form of the meteoric theory, the essential principle of which was that at some time long past the sun's initial heat was generated by the collision of masses gravitationally attracted to one another from distant spaces to build up its present mass; and the shrinkage due to cooling gave, through the work done by the mutual gravitation of all parts of the shrinking mass, the vast thermal capacity in virtue of which the cooling had been and was so slow. The rate of shrinkage corresponding to the present rate of solar radiation was $33\frac{1}{2}$ mètres on the radius per year, or one ten-thousandth of its own length on the radius per 2,000 years. Hence, if the solar radiation had been about the same as at present for 200,000 years, the sun's radius must have been greater by 1 per cent. 200,000 years ago than now. If we wished to carry our calculation much further back or forward than that time we must reckon by differences of the reciprocal of the sun's radius, to take into account the change of density. If in past time there had been as much as 15 million times the heat radiated from the sun as is at present radiated out in one year, the solar radius must have been four times as great as at present. If the sun's effective thermal capacity could be maintained by shrinkage till 20 million times the present year's amount of heat was radiated away, the sun's radius would be half what it is now. But the density which this would imply, being more than eleven times that of water, was probably too great to allow the free shrinkage to be still continued without obstruction through overcrowding of the molecules. It seemed, therefore, most probable that we could not for the future reckon on more of solar radiation than 20 million times the amount at present radiated out in a year. Also the greatly diminished radiating surface at a much lower temperature would give out annually much less heat than the sun in its present condition. These considerations had led Newcomb to the conclusion that it was hardly likely that the sun could continue to give sufficient heat to support life on the earth—such life as we were acquainted with, at least—for ten millions of years from now. In these calculations the density of the sun had been considered as uniform for the sake of simplicity. In reality, of course, there must be a wide difference between the density at the centre of the sun and the density at the surface; but it did not seem probable that the correction could add more than a few million years to the past of solar heat, and what could be added to the past would have to be deducted from the future. By the light of more recent calculation, and taking into account all possibilities of greater density in the sun's interior, and of greater and less activity of radiation in past ages, it would be rash to assume as probable anything more than 20 million years of the sun's light in the past history of the earth, or to reckon on more than five or six million years of sunlight for the future. As to the early history of the sun, five or ten million years ago it might have been about double its present diameter and an eighth of its present mean density, but we could not with any probability of argument go on continuously much beyond that time. It was impossible to help asking, however, What was the condition of the sun's matter before it came together and became hot? It might have been two cool solid masses which came into collision with the velocity due to mutual gravitation, or, but with enormously less of probability, it might have been two masses coming into collision with velocities considerably greater than those due to gravitation. If two cool solid globes, each of the same mean density as the earth and of half the sun's diameter, were given at rest at a distance asunder equal to twice the earth's distance from the sun, they would fall together in half a year. The collision would last a few hours, and in the course of it the globes would be transformed into a violently agitated incandescent fluid mass, with about 18 million years' heat ready made in it, and swelled out to possibly three or four times the sun's present diameter. If, instead of being initially at rest, two globes had a transverse relative velocity of 1·42 kilomètres a second, they would just escape a collision, and would revolve in equal ellipses round the centre of inertia. If the initial transverse relative velocity were a little less than 1·42 kilomètres a second, there would be a violent grazing collision, and two bright suns would come into existence in a few hours and commence revolving round their common centre of inertia in long elliptic orbits, the eccentricity of which would be diminished. If the initial transverse component relative velocity of the two bodies were just 68 mètres, the moment of momentum would be just equal to that of the solar system, of which 17-18ths was Jupiter's and 1-18th the sun's, the other bodies of the system not being worth considering in the account. Assuming the sun's mass to be composed of portions which were far asunder before the sun was hot, the immediate antecedent to its incandescence must have been either two bodies with details differing only in proportion and densities from the cases considered; or it must have been some number more than two—at the most, the number of atoms in the sun's present mass. The immediate antecedent to incandescence might have been the whole portions in the extreme condition of subdivision; or it might have been any smaller number of groups of atoms making up minute crystals; or it might have been lumps of matter like meteoric stones. For the theory of the sun it was indifferent which of these alternatives was accepted; but we could not but adopt the common opinion which regarded meteorites as fragments broken from larger masses, and we could not be satisfied without trying to imagine what were the antecedents of those masses. Nothing short of atoms seemed admissible as a theory of the primitive condition of things; and it was strange how we were brought back to the theory of Lucretius.

TURNING PULLEYS—LATHE FACE-PLATES.*

By Prof. JOHN E. SWEET.

SOME unfortunate experience in recent attempts to get pulleys that run true leads me to call attention to a method I believe to be the correct one, producing pulleys meeting the general demand that they shall be cheap and good. I mean where a common turning lathe is used for boring and turning. And here it may be pertinent to remark that the pulleys we have had reason to complain



about have been made at places where shaftings and pulleys are a speciality, and presumably finished by special pulley machinery. I will also take this opportunity to remark that I was told by a man who makes a business of the small pulley trade that they, on common lathes, could beat, in quantity and quality, any special pulley machinery he had ever seen, and that he had seen all he had ever heard of. From his statement of the number turned out in a day, I should judge they could. But to the point. Pulleys that wobble from $\frac{1}{8}$in. to $\frac{1}{4}$in. when set upon a ground mandrel and run on dead centres are not good enough, and the system upon which they are made, that renders it possible to make them so, must be wrong.

The plan that seems to me to be right is this: First, all pulleys to have six, or if very large nine, or if small three, arms; second, to have bolted to the face-plate three brackets, projecting out far enough to bring the rim of the pulley 1in. or more from the face-plate, and of such shape at their outer ends as will grasp an arm of the pulley, with set screws to adjust the pulley sideways and to hold it firm, and set screws to set pulley concentric. [The small engraving will represent Prof. Sweet's idea; as shown, it is applied to turning a balance wheel.]

With this system of holding, it is not possible for the latheman to spring the pulley in any way; and—what is of far more consequence—if the casting has any inherent strain, it will take care of itself when the roughing cut is taken off, and no letting up on the straps, after the roughing cut is over, is necessary or possible. Third, everything that is to be done to the pulley, both in the way of boring and turning, can be done at one setting, and if the brackets are set out near the rim, the driving power is the strongest possible; boring the hole too large or tapering is about the only way to make a poor job.

In setting pulleys, hand wheels, and, in fact, all concentric work that is to be turned outside, and not inside, the "truing up" should be done by the inside instead of by the outside, as is the almost universal practice, for the reason that then, when finished, the rim will be a practically uniform thickness. Another point—if there is any question about a piece holding up to size, if when set by the inside it will not then hold up to size, no amount of shifting will help it.

With a face-plate having three radial slots, the brackets can be set out and in to hold different size pulleys, and this brings up the question of face-plate slots, upon which lathe builders may well spend a moment's thought. We have one with fifty-three slots in the outer circle, and it would be a great consolation to us if the maker could be compelled to use it. It never comes right for anything. What there should always be is twelve, or a multiple of twelve, in the larger sizes. This number is always divisible by both three and four, and, when practicable, three should always be used, unless the piece to be treated is so strong as to be beyond the possibility of springing, or so weak that three points will not sufficiently support it; and then, in the first case, four are better, because a piece can usually be more quickly set on four points than any other number, and in the latter case enough points of supports must be used to hold the piece against the cut.

* From the *American Machinist.*

USEFUL AND SCIENTIFIC NOTES.

Carter's Rivet Pitch Calculator.—This instrument has been designed with a view to afford boiler makers, draughtsmen, and engineers generally a simple, accurate, and comprehensive means of finding a theoretically correct pitch for rivets, without the use of cumbrous tables or formulæ. By a simple movement of the instrument may be found at once, without calculation, such a pitch as will give equal strength of plate and rivet; or the pitch being given, the relative percentages of strength of plate and rivet in the joint may be found. It comprises the requirements of the Board of Trade and of Lloyd's Surveys, and is adjustable to any proportions or allowances desired by the designer. The size is about $5\frac{1}{4}$in. by 2in., and we think it will be found of service.

McKellar's Improved Horseshoe.—An improved horseshoe has been designed by Mr. D. McKellar, Nurseryman, of Oxford-gardens, Notting-hill, W., which promises to become of considerable utility. The patent is not yet completed, so that we cannot fully describe it; but the shoe is so made that a frost plate can be readily slipped over it, while the winter shoe can be worn as an ordinary shoe without the frost plates. A modification provides a shoe excellently adapted for cab horses, &c., as it allows of any description of pad being secured to the hoof. A horse shod in this manner is prepared for all kinds of work, as the plates can be worn regularly or be securely attached to the shoes in a few minutes.

The Coal Supply of London.—According to the statistics prepared by Mr. J. B. Scott, Registrar of the London Coal Market, it seems that in 1886, London imported from different parts of the country by sea 4,671,127 tons, as against 4,563,966 tons in 1885; and by railway and canal, 7,128,380 tons in 1886, as against 7,081,488 tons in 1885. After making due allowance for exports, there has been a total increase in the coal trade within the London district during the present year of 150,043 tons. One is struck by the magnitude of the trade, and also by the fact that the price of coal on the London market has been low during the past year, the average price, including dues, being only 16s. 2d. per ton.

ANOTHER new route to Australia will soon be available. The completion of the new Transandine Railway, now in progress, will, it is expected, enable the time occupied in travelling from this country to Australia to be shortened by at least fourteen days; the route being to Buenos Ayres by steamer, thence by rail to Valparaiso, and thence by steamer again to Australia.

SCIENTIFIC SOCIETIES.

ROYAL METEOROLOGICAL SOCIETY.

THE monthly meeting of this Society was held on Wednesday evening, the 19th instant, at the Institution of Civil Engineers, 25, Great George-street, Westminster, Mr. W. Ellis, F.R.A.S., President, in the chair.

Mr. J. Willis-Bund was elected a Fellow of the Society.

The following papers were read:—

(1) "On the Identity of Cloud Forms all over the World; and on the general Principles by which their Indications must be Read," by the Hon. R. Abercromby, F.R.Met.Soc. The author illustrated the fact of the identity of cloud forms by exhibiting 37 photographs of different kinds of clouds which he had taken in various longitudes, and in latitudes ranging from 72° N. to 55° S., including some actually on the Equator. Cumulus was shown to be the commonest cloud in the Tropics; cumulo-stratus and cirro-stratus in the Temperate Zone; and stratus and fog in the Arctic Regions. The author considers that 90 per cent. of the skies all over the world might be described by the seven well-known types of cloud—cumulus, stratus, cirrus, cirro-stratus, cirro-cumulus, cumulo-stratus, and nimbus; if by cirro-cumulus, fleecy-looking clouds are denoted. Although the forms are alike, the prognostic value of the same shape of cloud is not identical everywhere, for while woolly clouds indicate fine weather in England, they denote rain in Italy. The author showed that the form alone of clouds is equivocal, and that the indications of coming weather must be drawn not only from the form but also from the surroundings of a cloud, just as the meaning of many words can only be judged by the context.

This paper was rendered most interesting by the photographs being thrown on the screen by Mr. B. C. Wainwright, F.R.Met.Soc., from a limelight lantern.

(2) "On the Cloud to which the Name 'Roll-Cumulus' has been Applied," by the Hon. R. Abercromby, F.R.Met.Soc. The author thinks that this cloud should be reported as "stratus" or "cumulo-stratus," according as the component masses partake more or less of the character of one or other of these clouds.

After the reading of these papers, the annual general meeting was held, when the report of the Council was read by Dr. Tripe, which showed the Society to be in a satisfactory condition. The number of Fellows was 524.

The President, Mr. W. Ellis, in his address, drew attention to the remarks made by Mr. Hawksley at the meeting of the Royal Meteorological Society on June 16th last, in which, after acknowledging the indebtedness of engineers to meteorologists for the information collected by them concerning floods and rainfall, without which, as he said, it would not be possible for engineers to carry on their work efficiently, proceeded to urge on meteorologists the need of more investigation into the causes of the various phenomena connected with their science. The president suggested that this is just what meteorologists were always endeavouring to do, pointing out how great an amount of labour had already been thus expended, if not always wisely, at any rate with every desire to trace out connections and causes, any want of success being due rather to the difficulties of meteorological inquiry than to any other cause. Referring then to the connection of the physical sciences, and especially those of astronomy, terrestrial magnetism, and meteorology, he drew attention to various contrasts and relations existing between them, mentioning how in astronomy strict mathematical processes may be employed, whilst in meteorology tentative methods have to a great extent to be relied on—a state of development through which astronomy itself had in earlier ages also to pass, giving hope that in the confessedly difficult subject of meteorology we may in time pass from present systems to others more logical. There has already been progress; the preparation of a daily synoptic weather chart, made practicable by the aid of the electric telegraph, would have been impossible not so very many years ago. Again, in astronomy the power of assimilating observations, as it were, is mostly in advance of the observational power, rendering ever greater instrumental means desirable. Not so in meteorology, for the purposes of which instruments can be constructed with accuracy beyond the power of adequately employing them, of which the difficulty of ascertaining the true temperature of the air is an illustration. This, indeed, troubles also the astronomer, the element of air temperature being one that enters into the calculation of astronomical refraction, besides which he has in various other ways to reckon with temperature effects. After referring to some popular notions on weather changes as related to the sun and moon, as well as to more systematic endeavours made to discover relations, in general insignificant, between position and periods of the moon and different meteorological elements, the president remarked that the modern meteorologist had happily found a wider sphere of work, for troubling himself less about cycles and periods, he had seen the necessity of studying, by the aid of synoptic charts, the complex and broad phenomena of the atmosphere in all their varied relations. Passing on to consider some relations between meteorology and terrestrial magnetism, he mentioned some analogies existing between the meteorological element of temperature and the motion of the magnetic needle, as regards their diurnal and yearly variations; proceeding then to discuss to some extent the relation between solar spots, terrestrial magnetism, and meteorology, pointing out that whilst in certain broad features the relation with magnetism was very striking, that with meteorology, so far as we are able to interpret the results obtained, is comparatively uncertain. Some allusion was made also to earth currents as related to magnetic phenomena. Before concluding, the president, viewing the present outlook as regards meteorology, spoke of the new and higher meteorology that, in spite of the difficulties of the subject, is now springing up, and referring to the various international congresses as having promoted uniformity of action and division of labour, and that meteorology now, perhaps more than ever, stood in need of combined action among its workers; and alluding to the idea of federation of which of late so much has been heard, suggested that a permanent federation of the meteorologists of different countries might regulate meteorological action and inquiry throughout the world, and so promote the better elucidation of meteorological laws, whilst also accumulating materials for the future discussion not only of the meteorology of the earth as a whole, but also of any periodical or secular changes, however produced, that might be proceeding thereon.

ROYAL MICROSCOPICAL SOCIETY.

THE fourth meeting of the session was held on the 12th inst. at King's College, Strand, the President (Dr. Dallinger, F.R.S.) in the chair.

Mr. J. Mayall, jun., at the request of the President, directed the attention of the meeting to 11 photo-micrographs which had been sent by Dr. Van Heurck, and which the latter thought showed results of exceptional merit. The one of *Amphipleura pellucida* by transmitted light was rather striking; it showed apparently two series of lines which were resolved into dots, and, so far as he was aware, this was the best of the kind which he had yet seen. But Dr. Van Heurck did not say whether it was taken from a specimen mounted in a dense medium or not, and he thought also that several important questions of technique were omitted which it would have been very useful to have had mentioned. In the pamphlet which accompanied the photographs, Dr. Royston-Pigott was quoted to the effect that they were "quite free from what used to be called 'diffraction spectra,' which now here have no existence whatever"; but, on examination, unless he was much mistaken, they had been painted out, or otherwise blocked out, from the negative, so that Dr. Royston-Pigott, in his remarks upon this supposed fact, had made what the French called a *boulette*. If it was desired to give such photographs a real value, the background should not be interfered with, and a small tablet should be left on which should be written, so as to print with every impression, the particulars as to magnification, mounting, and other data for identifying the object, which it was essential to be in possession of in order to form any reliable opinion. As regarded the longitudinal lines of *Amphipleura pellucida*, as shown in the untouched negatives of these photographs, Dr. Van Heurck said he had submitted them to Prof. Abbe, who replied that as they appeared closer than the diffraction lines, that was a satisfactory demonstration of their existence in the object. Unfortunately, the data which enabled Prof. Abbe to express this judgment did not exist on the prints sent to the Society by Dr. Van Heurck, in consequence of the objectionable process he had adopted of stopping off the natural backgrounds. In lieu of the natural backgrounds, which left the outlines to be seen exactly as photographed, this plan of stopping off the backgrounds left the field white, but at the sacrifice of the natural outlines. This might add somewhat to the mere appearance of the photographs, but must certainly diminish their scientific value. In the case of *P. angulatum*, he thought the photograph rather failed to show the details satisfactorily. It would have been very much better if only a small portion of the valve had been shown, including the fracture. As to the photograph of *P. angulatum* in which a central spot was shown, all who were familiar with the object were aware that they could get the appearance of a central spot or not according to how they looked at it. It was a question of change of focus. *Surirella gemma* he thought was not better shown than in Dr. Woodward's photographs. Then there were photographs of Nobert's lines, which were said to be those of the 18th and 19th bands; but here again there was nothing to enable one to identify them or to say that they were not the 14th or 15th bands.

The President, in thanking Mr. Mayall for his remarks, said it must be obvious to all that it would be of immense advantage to have the data by which alone they could form anything like a correct judgment as to the value of these, or, indeed, any other specimens of photo-micrography. He thought also that it would be of advantage if they could have the opportunity of comparing these with those of Dr. Woodward.

Mr. Crisp also referred to Dr. Royston-Pigott's misunderstanding as to the diffraction spectra of the Abbe theory.

Mr. J. Beck said he had not looked at any of the photographs except that of *Amphipleura*; but he should say that the manipulation which it had gone through had entirely destroyed its value.

Dr. Miller called attention to a photo-micrograph of *P. angulatum* taken by M. Nachet in 1867, which was fully as good as the one now shown.

The President stated that it was proposed by the Council to fill up the vacancy in their list of Honorary Fellows by electing Mr. P. H. Gosse, F.R.S.

Mr. M. Pillischer exhibited his new "Kosmos" microscope, which was described by Mr. J. Mayall, jun., as being made on the Continental model with a short body and a direct-acting screw, the screws being bevelled off and the corners rounded. There was a very symmetrical foot, and the finish given to the instrument made it very nice to touch. The mirror was made with a neat swinging motion, and was of a somewhat shorter focus than those generally in use, and it was claimed that as regarded general finish and capability, it would compare favourably in economy of price with any others.

Mr. T. Charters White read a note on "Tartar from Teeth of the Stone Age," numerous preparations being exhibited in illustration.

Mr. Crisp exhibited a cylinder of glass made at Jena, and described by Prof. Exner in the December No. of the *Journal*, p. 1,065. Though it had plane ends it acted as a concave lens, the reason being that it was of varying density from the centre to the circumference. It solved some of the questions which had been raised, as to the images formed in insect's eyes. Mr. Crisp also explained Prof. Exner's method of preparing similar cylinders from celloidin and gelatin, when the effect of convex lenses was obtained.

Prof. Bell said that in the interests of the particular branch of science to which he was devoted, he might mention that a little knowledge of histology by certain of the observers mentioned would have shown that the cornea was quite flat in the case of the crayfish, which had managed to see very well for a good many years.

Mr. Crisp directed the attention of the meeting to enlargements on the black-board of the figures of enormous microscopes in Schott's "Magia Naturalis," 1657. These had long puzzled microscopists, who were at a loss to understand what could be the object in making microscopes of the large size which was indicated by the comparison with the observers represented as looking through them. Having found in an old book sent to him by Prof. Abbe—Traber's "Nervus Opticus," 1690—what were undoubtedly meant for drawings of the same microscopes, the mystery was solved, for if Schott's figures of whole-length men were rubbed out and single eyes were substituted for them, as Traber did in his drawings, the scale of the microscope represented was, of course, strikingly altered, and it was seen that they were small hand microscopes after all. Schott's draughtsmen probably had too much of an artistic eye.

Mr. J. B. Medland exhibited and described his new portable cabinet for microscopic slides, in which twelve dozen slides were packed in a space 11in. by 5in. by 3½in.

The President thought this was a very simple and practical mode of making a compact cabinet, which would commend itself at once to all who examined it.

Mr. Crisp exhibited Stein's electric microscope.

Mr. A. W. Bennett gave a *résumé* of his paper on "Freshwater Algæ (including Chlorophyllaceous Protophyra) of North Cornwall," with description of six new species, illustrated by coloured diagrams.

The President said they must all feel indebted to Mr. Bennett for his very interesting communication, and they could not fail to note how very much pleasure there must have been added to a holiday in the case of one who had made himself so thoroughly master of this subject. He thought this paper was full of encouragement to others, because every young student had the ditches and ponds open to him, and there was the opportunity for all to add to their physiological knowledge of this interesting and beautiful group.

Mr. J. Mayall, jun., said that since the previous meeting of the society he had availed himself of an opportunity to visit Jena, which Mr. Crisp aptly

termed the "Mecca of microscopists," where during about a fortnight he had been the guest of Prof. Abbe. Every facility had been presented to enable him to follow the technical processes employed in the manufacture of microscopes in Messrs. Zeiss's optical and mechanical workshops, and in the production of optical glass in the Jena Optical Glass Works, and his impression was that it would be hardly possible to overrate the skill in organisation there displayed for the purposes in view. Messrs. Zeiss employed upwards of three hundred assistants in a series of workshops so arranged that those departments where delicate work was being produced —where the vibration of steam machinery would be a serious drawback—were quite separate from the departments where steam-power was employed. Messrs. Zeiss had found it advantageous to make their own brass castings, and hence had established a foundry on their premises. He had seen the various heavy kinds of lathe work and fraising in full operation with steam-power. The parts of the microscope-stands where this and other mechanical work was being executed were usually given out in sets of ten, and in general the system of piecework was in vogue throughout the workshops. With regard to the optical work, only a very small portion was produced by the aid of steam-power; for instance, the plane surfaces of eyepiece lenses, which were worked together in large sets, and the glass-slitting by means of rapidly-revolving iron discs charged on the edges with diamond fragments. The glass slitting machine was largely employed in the preparation of prisms of the different samples of glass for the determination of the refractive and dispersive indices. By means of the glass slitter, the plates of optical glass, as received from the glass works, were cut to the various thicknesses required, and then, by means of ordinary American wheel-cutters, the thin strips were cut into squares of the sizes required. The squares were placed in suitable trays in the storeroom, whence they were given out to the glass-grinders, together with the necessary tools and the gauges belonging to them. The glass-grinders snipped the squares to approximately the disc shape, and then cemented them each on a suitable block, and ground and polished the surfaces, the metal tools being attached to foot-lathes with vertical spindles passing through suitable deep trays, in which the refuse emery, &c., was caught, and the workmen were generally seated. For testing the accuracy of the finished surfaces, Fraunhofer's method was employed, which consisted in providing for each curvature required a pair of highly-finished standard convex and concave surfaces worked in rock-crystal, of which the radii had been accurately determined by means of a spherometer of great precision, the perfection of the curvatures being shown by the symmetrical formation of Newton's rings when the surfaces were pressed in contact. Each surface, as finished, was tested by contact with the corresponding standard surface of rock-crystal, and the polishing was continued until the required degree of accuracy was reached. He (Mr. Mayall) was aware that Fraunhofer had employed this method of testing the accuracy of spherical surfaces for telescopes, using standards made of glass. Prof. Abbe informed him that Dr. Hugo Schroeder had suggested the advisability of making the standards of rock-crystal, instead of glass, for testing microscope lenses, on the ground of its much greater durability where required to be in such constant use. Each workman was also provided with a contact-measurer, by which he was able to determine the thickness of the lenses, and thus approximate to the required thickness within a small fraction of error. An experienced foreman superintended this department, and was responsible for the accuracy of all gauges, &c. Mr. Mayall said he had been much interested to see these methods of precision in regular daily use in Messrs. Zeiss's workshops, the more so from the fact that for much of the optical work lads were employed, who thus obtained admirable training for the more difficult branches on which they entered later on. He had also witnessed the processes of centring the separate lenses, and reducing them to the required diameters; then the cementing into combinations and the mounting in metal cells, with its attendant further process of centring. He had also watched the whole process of manufacturing a front lens for an apochromatic one-eighth homogeneous immersion, from the grinding to the complete mounting in its cell, centring, &c., the lens being somewhat greater than a hemisphere, and the figure being tested in the standard concave of rock-crystal as he had previously described. The rapidity and dexterity shown throughout the execution of this delicate work had most favourably impressed him as to the high character of the training in Messrs. Zeiss's workshop, for it should be noted that the production of such work was not confined to one pair of hands, as generally obtained in England, but was being executed by several—workmen of special aptitude, doubtless, but still such as the system of training there adopted brought to the fore in sufficient number to meet the demand, even in so large an establishment. He had also witnessed with special attention the methods employed for testing the finished objectives; but there, of course, so much depended on the education of the eye and judgment, that he could not venture to criticise, not having himself practised with Prof. Abbe's silvered plate method. He understood, however, from Prof. Abbe that the method enabled the director of that department to give precise instructions as to alterations needed to reach a certain standard of excellence. He must not omit to refer to the photomicrographic department, to which Dr. Roderick Zeiss had given very special attention. A separate building had been erected for these experiments, and massive concrete blocks were provided to support the installation of the electric light and projection apparatus, &c., as free as possible from vibration. Here he had seen a number of images of test objects, &c., projected on a screen by means of an arc lamp of 1,200c.p., using various objectives, from 1in. to $\frac{1}{20}$in. focus. In some instances the higher degree of achromatism attained in the new apochromatic objectives was unquestionably shown, and he had no difficulty in admitting that on the whole the projection images were the best he had ever seen by artificial light. In view, however, of the extreme difficulty—impossibility he might say —of controlling the arc lamp, of maintaining a steady and equal light even for a space of one or two minutes, he thought for purposes of photomicrography it could not be commended, especially not for producing large negatives by direct projection. He had long held the opinion that the best photo-micrographs were obtained by making small negatives by direct projection, negatives just large enough to exhibit the points sought to be demonstrated; if, then, it were desirable to produce a further enlargement, the small negative could be magnified by an ordinary photographic process. In this way the best photo-micrographs by Dr. Van Heurck, of Antwerp, were produced, and the most difficult results were obtained by using sunlight. The main purpose of his visit to Jena, however, was to submit to Prof. Abbe's examination a number of the best English objectives, whence he could accurately estimate the standpoint of excellence from which English microscopists would criticise the new apochromatics produced at Jena. In furtherance of this purpose Mr. Mayall said that the President of the Society (Dr. Dallinger) and the senior secretary (Mr. Frank Crisp) had placed at his disposal the best objectives in their collections. Mr. Nelson had also most courteously requested him to select from his fine collection any objectives which he thought would worthily represent English optical work. From these collections, and sundry examples from his own, Mr. Mayall said he believed he had been able to carry out the intention of his visit to Jena; and he thought Prof. Abbe was now as vividly aware of what was meant in England by "critically good images" as possibly could obtain under the circumstances. He must, of course, mention the fact that he took with him to Jena his large Powell and Lealand microscope and accessory apparatus. If his visit to Jena resulted in inducing Prof. Abbe to withdraw his frequently-expressed depreciation of the value of the achromatic condenser—and he had reason to believe this would be one of the practical results following upon his visit—he (Mr. Mayall) should consider his journey not wholly fruitless in advancing practical microscopy.

Referring to the Jena Optical Glass Works, Mr. Mayall said they were under the management of Dr. Otto Schott, who appeared to have thrown his energy thoroughly into every detail of their organisation, which had so favourably impressed the German Government that large official grants of money had been made in aid of the experiments suggested by him. He understood Dr. Schott to say the experience he had gained in the experiments made with the consent of the Government—experiments which had all been most carefully classified and recorded—enabled him now to undertake to furnish any kind of optical glass according to sample supplied to him. On receiving such a sample, he proceeded to analyse it both optically and chemically, and then, from his registrations of experiments already made, he was able at once to select the elements and conditions required to arrive at the same result. The new kinds of glass employed in Prof. Abbe's apochromatic objectives were produced at these Glass Works, as also the glass employed by Messrs. Powell and Lealand for their new apochromatics. Dr. Schott expressed his conviction that several of his new kinds of glass would be found of great importance in the construction of photographic lenses; he also said that Steinheil, the well-known optician of Munich, had already adopted its use largely. Such a fact ought not in his (Mr. Mayall's) opinion to be neglected by our makers of photographic lenses; for, assuredly, if one of them could succeed in producing lenses with a given ratio of aperture to focal length, but giving a larger and flatter field than had hitherto been seen—and the apochromatic microscope-objectives showed how advance in that direction had been made by means of the new glass—the demand for such improved lenses would be practically unlimited.

The President said he thought the Fellows would agree that their Society was sufficiently mature to be entitled to get the highest possible perfection obtainable with respect to its apparatus and appliances, so that whatever would contribute to the attainment of any increase in this perfection could not fail to be of the greatest interest to them. From what they had just heard, he felt sure that Mr. Mayall's visit to Jena had not been in vain. His communications had been received with appreciation, and would no doubt be cogitated upon, and would give rise to an amount of interest and attention which would be certain to bear fruit at no distant date in the form of still further increase in the perfection of the very admirable work which they were already so familiar with.

Dr. A. C. Stokes's paper on "Some New American Fresh-water Infusoria," was read by Prof. Bell.

Mr. Crisp read the list of nominations for Council and officers for election at the anniversary meeting.

Mr. Hembry and Mr. Vesey were elected auditors of the treasurer's accounts.

SCIENTIFIC NEWS.

ONE of the most famous mechanicians of this or any century has gone to his rest. Sir Joseph Whitworth died at Monte Carlo on the 22nd inst. in the 84th year of his age. Born at Stockport on Dec. 21, 1803, Joseph Whitworth began his business life in his uncle's cotton spinning mill, where he rapidly acquired a complete knowledge of the machines, and became so useful that he was practically the manager long before he had reached his twentieth year. At that age he ran away (his uncle would not part with him), and obtained employment in some of the Manchester shops, migrating subsequently to London. His skill was soon appreciated at Maudslay's, and there, undeterred by the chaff of his bench mates, he constructed his first surface plates, which would alone have sufficed to make his name known, as it is, in every workshop in the world. From Maudslay's Whitworth went to Holtzapffel's, and afterwards joined that distinguished mechanician, Clements, who is said to have taught him how to make a true screw. In 1833 he returned to Manchester, and set up as a "tool maker from London," and that was the commencement of a business which has had an important effect on the mechanical progress of the world. In the Great Exhibition of 1851 Mr. Whitworth was represented by specimens of his true planes and his millionth measuring machine, but he had previously publicly described his method of manufacturing the former in a paper read before the British Association at Glasgow in 1840, and in the following year gave an account of his uniform system of screw-threads at a meeting of the Institution of Civil Engineers. Sir Joseph Whitworth's inventions in rifled small arms and in guns are well known; but he will be best remembered as the first designer of accurate tools and measuring instruments, and as the munificent founder of the Whitworth Scholarships.

The death is also announced of Mr. Edward Livingston Youmans, a well-known American scientific lecturer and writer. He was born at Colymans, New York, in 1821, and suffered all his life from defective vision—so much so that he invented a machine to assist him in writing. Dr. Youmans was the originator of the "International Scientific Series" and the *Popular Science Monthly*, which latter he established in 1872.

According to Circular No. 13 of the Liverpool Astronomical Society, the star referred to in No. 12 (see p. 450) is rapidly decreasing, as on Jan. 22 it was found to be barely 10 mag. by Mr. W. H. St. Q. Gage.

Under the heading "The New Comet," the daily papers publish a telegram from Melbourne, which reads: "The tail of the comet of the first magnitude, which has become visible here, projects 30 deg. above the south-west horizon, and was first observed on the night of the 19th inst. The nucleus is below the horizon, and is supposed to be in the constellation Microscopium in R.A. about 21h. 40m. south, the tail extending to Alpha Toucanæ. The comet is seen nightly. It is not bright, although it is distinctly visible to the

naked eye after twilight. No positions have yet been determined. The comet is probably invisible in Europe."

According to a correspondent of a San Francisco paper, the crown and flint lenses arrived safely at the Lick Observatory on Dec. 27, and were at once unpacked. The glasses were then mounted in a cast-iron cell inlaid with silver, with a space of $6\frac{1}{2}$in. between them. The cell, with its valuable additions, weighing altogether 600lb., was then placed in a vault in the north room, where every precaution had been taken to prevent injury from damp, and there the lenses will remain until the mounting is ready for them. It is probable that the great telescope and the observatory will be handed over to the trustees of the University about the 1st of September next.

At a recent meeting of the Royal Society, a paper by Prof. J. W. Mallet, of the University of Virginia, was read, in which the author gives an account of his investigations of some volcanic ash ejected from Cotopaxi during the eruption of July 22-23, 1885. In the dust he detected silver—a metal previously unrecognised amongst volcanic products. The dust was collected at a point on the Pacific Coast, about 120 miles west of the volcano, where it fell to the depth of several inches. It appears that about one part of silver is present in 83,600 parts of the ash, or two-fifths of an ounce troy per ton. Although this proportion seems insignificant, the mass of ejected ash was so vast that it really represents a large quantity of silver in the total bulk. Lead, which had been found in ash from Cotopaxi in 1878, was not detected in that of 1885.

At the meeting of the Royal Society of Edinburgh last week, Mr. J. Murray read a paper on "The Total Rainfall on Land of the Globe, and its Relation to the Discharge of Rivers." Investigations show that the total amount of rain falling upon the land-surface of the globe is 29,350 cubic miles annually. Of this amount 2,243 cubic miles of rain fell on the inland drainage areas of the globe, which had an area of 11,486,350 square miles, and as no water was discharged from them into the ocean, it followed that all the water which fell as rain must be again returned to the atmosphere by evaporation. Should the water accumulate in these areas into lakes, and these lakes show a slight annual increase in size, then the rainfall must be regarded as greater than the evaporation; but when, as in the case of the great Salt Lake of North America, the size of the lake slowly diminished, the evaporation over the basin must be greater than the rainfall. The total weight of substances carried to the ocean by rivers each year is calculated by Mr. Murray at over five thousand million tons.

According to a telegram from Melbourne, intelligence has been received from Brisbane which states that the latter city was visited by a cyclone on the 20th and 21st inst. which did great damage, rain having fallen to a depth of 20in.!

Last week an experimental trip was made with the Elieson electric locomotive on the tramway which runs from Stratford Church to Manor Park, a distance of about two miles, and if a Bill is passed in the present session of Parliament, it is intended to run electric locomotives alternately with the horse cars. The locomotive carries 80 storage cells, which are charged at the Stratford depot, and is propelled by means of an Elieson electromotor placed under the flooring of the car; the motor itself revolves, instead of being a fixture, as is usual. A prolongation of the spindle of its armature carries a pinion which gears into a circular fixed rack. Motion is transmitted to the road wheels through bevel gearing. The total weight of the locomotive is $6\frac{1}{2}$ tons, and that of the tramcar empty $2\frac{1}{4}$ tons, or with its full complement of 46 passengers 5 tons. But on the occasion of the actual run there were about 60 passengers on the car and engine, so that the total weight moved was in excess of 12 tons. It cannot be long before electricity will be used extensively for propelling tramcars; but it would seem to be cheaper to have self-contained motor cars rather than to employ a locomotive. On this point, however, experience will soon show which is the more economical.

Mr. J. T. Bottomley has, it is said, made a perfect pendulum by suspending a lead shot by a single fibre of cocoon silk in a vacuum produced by a Sprengel pump. The shot, one-sixteenth of an inch in diameter, weighs one-third of a gramme, is suspended by a 2ft. fibre, and is placed in a tube $\frac{3}{4}$in. internal diameter. It has a vibrational range of $\frac{1}{4}$in. on each side of mid-position, the vacuum being equivalent to one-tenth of a millionth of an atmosphere.

The Council of the Royal Geographical Society having communicated with the Vice-Chancellors of Oxford and Cambridge, urging the claims of geography to a further recognition in the universities, and offering to establish or make a contribution towards a geographical chair or readership, the proposal met with a favourable reception, and it is not unlikely that another step will be taken by the council, with the consent of the Education Department—viz., the award of prizes to pupils in Board Schools who reach a certain standard in geographical knowledge.

In the course of the Greenock annual lecture "in honour of the birth of James Watt," Mr. R. Duncan, shipbuilder, expressed the belief that the Queen's reign might see "steamers eight hundred feet long making the Atlantic passage at twenty-five to thirty miles an hour." In his experience as a shipbuilder there was a certain relation of speed to length, and he gave this rule—the minimum length should be "not less in feet than the square of the speed for which she is designed." A vessel to make ten knots should be at least a hundred feet long; and if twenty knots speed be desired the length should be four hundred feet. Torpedo boats are presumably an exception to this rule.

Last week in Glasgow a new train of close-coupled coaches, lighted with gas and warmed with hot-water pipes, made some trips on the Glasgow and Cathcart District, and we understand it is the intention of the Caledonian Railway Company to supply other local lines with services of a similar character.

The citizens of Liverpool appreciate the importance of an engineering laboratory attached to the University College, for Sir A. B. Walker having given £15,000 to the endowment fund, Mr. T. Harrison has followed with £10,000 to endow a chair of engineering, which is at present ably filled by Prof. Hele-Shaw.

The efforts of Sir S. Maryon-Wilson in promoting fish culture in the Sussex rivers have proved successful, for a batch of young Loch Leven trout were turned into the Ouse about seven years ago, and some remarkably fine specimens have recently been seen in the stream near Searles. One was captured and placed in the lake: it measured 30in. and weighed over 10lb.

In a lecture recently delivered by Dr. F. Day' C.I.E., a warning was given to those who think of introducing the Indian cat-fish to British waters, for the doctor placed a specimen in an aquarium, when it rushed at one of the carp, seized it by the middle of the back and shook it as a dog does a rat until it was dead. The cat-fish it seems destroys simply for the sake of killing, not to supply itself with food.

We mentioned some little time ago that the Prince of Monaco had commenced a series of experiments designed to test the velocity of currents in the North Atlantic. Admiral Bouquet de la Grye has recently made a report to the Paris Academy of Sciences, in which he says that, of 500 little caskets or vessels launched in deep sea off Cape Finisterre, 12 arrived on the French coast a little below Arcachon, after an interval which would appear to show a daily rate of travel of about six miles. The temperature of the water was also observed, and the Prince found that in the Bay of Biscay, at a depth of about 500ft., the temperature of the water was lower than at the corresponding depth off the Portuguese coast.

A report on the employment of salicylic acid in food has been presented by M. Vallin to the French Government, in which it is stated that the continuous taking of even small quantities of salicylic acid, or its derivatives, is injurious to health, especially in the case of aged persons and those whose renal and digestive organs are not perfectly sound.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE "NAUTICAL ALMANAC" FOR 1890—THE GREAT LICK OBJECT-GLASS—A NEW FORM OF METEOROLOGICAL FOLIE—GEN. DE LISLE'S GEODESICAL TABLES—THE NORTHUMBERLAND EQUATOREAL—FOCUS OF LENSES—STARS IN DAYLIGHT—THE GNOMONIC PROJECTION.

[26756.]—THE preface of the *Nautical Almanac* for 1890, which has just appeared, characteristically begins with the words, "The contents and arrangement of the *Nautical Almanac and Astronomical Ephemeris* for the year 1890 are the same generally as those of the preceding year." Just so. As I have previously observed, anything more utterly mechanical than the way in which the data for our National Ephemeris are annually ground out it would be difficult to imagine. If Dr. Hind ever condescends to examine the Ephemerides issued by other countries, he might with advantage consult the *American Ephemeris and Nautical Almanac* for 1889, as affording him a model on which he might found some very distinct and appreciable improvements in the work over which he presides. There even such details as those of the orbits of the satellites of Mars, Jupiter, Saturn, Uranus, and Neptune are rendered more useful and intelligible by wood engravings drawn to scale. I mention this as a single illustration of the attention paid to the general usefulness of the publication. For the rest, the old erroneous prediction of the phenomena of Jupiter's satellites are repeated; while the admittedly wrong dimensions of the Saturnian system are perpetuated. Perhaps this last piece of inattention is the less defensible of the two, inasmuch as the correction of the chronically misleading details requires no elaborate theoretical computation. In the case of Jupiter's satellites, it would seem that gravitational astronomy is at such an extremely low ebb in England, that until (what Professor Pritchard generalised as) "some German" gives us more correct tables than the 51-year-old ones of Damoiseau in use in Verulam Buildings, we must be content, "stare super vias antiquas," and to go on in the old dreary, blundering way.

Remembering the old proverb that "there is many a slip between the cup and the lip," I am gratified to read the inclosed telegram in a Californian newspaper kindly sent me by a friend:

"The Lenses of the Lick Telescope.—San Jose, Dec. 27—[Special.]—The great lenses of the Lick Observatory arrived at Mt. Hamilton at 1.30 this afternoon. They were found in fine condition, and were placed in the fireproof vault."

Let us hope that the time is now close at hand when this marvellous specimen of optical skill will be used for the advancement of our knowledge of the visible Universe. It would appear that there were no less than twenty successive failures in the attempts of the Feils, sons and father, to produce the discs from which this colossal object-glass has been formed. The third lens, for converting it into a photographic objective, is still in process of manufacture. Before the star-maps taken with 3ft. of aperture more than 4,000ft. above the sea-level, the hitherto unapproachable efforts of the MM. Henry Frères must fall into insignificance.

"A prophet is not without honour, save in his own country," and it really would appear that my slight want of faith in the absolute infallibility of M. Folie, the Belgian Astronomer Royal, is shared by some of his own countrymen, if I may judge from articles which have appeared in two of the Brussels newspapers, *La Chronique* for January 5, and *La Réforme* for January 10. It would seem that M. Folie has brought forth a brochure entitled "Petite Climatologie de l'Amateur et de l'Agriculteur Belges," which is very much more teleological than scientific. As I have not seen the book myself, I don't know whether the Saints figure in it (as they did in the notorious *Annuaire*,

of the Brussels Observatory for 1886, with its astounding "Commencement des Saisons," and so on), and, if so, which is the watery, which is the hot, and which the flatulent one?

I spoke (in letter 25555, Vol. XLIII. p. 121) in terms of commendation of some excellent tables for geodesical calculators, which had been computed by General De Lisle, R.E., from Col. Clarke's spheroid. I am sincerely pleased to find, from General De Lisle's kindness in forwarding me a few copies, that these have already run into a second edition. In it a very few trivial typographical mistakes (chiefly in the differences between the logs. of ρ) have been corrected, and possessors of the first edition may possibly care to go to the trivial cost of a new copy rather than to hunt through them to correct three or four figures with their pens. To all practical astronomers and geodesists who omitted to supply themselves with these tables originally, I would only say "Procure them as soon as you can." They are indispensable to all who wish to compute the true length of the radius of curvature of the earth in any given latitude, the parallactic angle (needed in so many astronomical calculations), and so on. It may not be wholly useless to note that in reproducing, in old figures, the formula for the logarithm of the earth's radius on the title-page the — mark over the index of the log. of ·0000018975 has dropped out, and it reads 6·27817685. This *is* remediable with a pen, though.

Someone has been writing to one of the morning papers contrasting, inter alia, the attention paid to astronomy at Oxford with the stagnation of that science at Cambridge, adducing as an illustration the fact that on going a short time since to see the Northumberland Equatoreal, he found puddles upon the floor of the room! It strikes me that a dome must either be brand-new or constructed upon some novel principle to keep out such snow as we have had within the last three or four weeks.

In reply to query 61386 (p. 441), the actual focus of a lens is the distance from the centre of the lens to its burning point, and *not* from the back of it. "Back focus" is new to me; it probably signifies the distance between the back of the lens and its focus for parallel rays. "Equivalent focus" is used in connection with two, or more, lenses in combination, which are said to have an equivalent focus to some given single one.

If "Dubitans" (reply 61101, p. 457) waits until the middle of August, he may, knowing her exact position in the sky, see Venus distinctly "in the open" in brilliant sunshine. Malgré his doubt, the cutting off of all extraneous light by a long dark narrow tube, such as is formed by a deep well or high chimney, does enable the observer to perceive a star of the first magnitude by daylight.

Premising that the gnomonic projection is a very bad one for a map of any place of less than about 60° latitude, distorting as it does proportions so terribly towards the margin of the map, I may just say, in reply to "K. E." (query 61487, p. 465), that the meridians are straight lines passing through the projection of the pole, which is, of course, on the line of projection of the principal meridian, and distant by an amount = radius into tan. principal polar distance (in his case 35°). But now comes the difficulty of this species of projection. All circles of latitude whose polar distances are less than the angle between the polar radius and that of the principal point are projected into ellipses; the one which has its polar distance identical with this angle is a parabola, and the rest are all hyperbolas! The projection of the principal meridian is the principal axis of all these curves. Save for a circumpolar map, the game is assuredly not worth the candle.

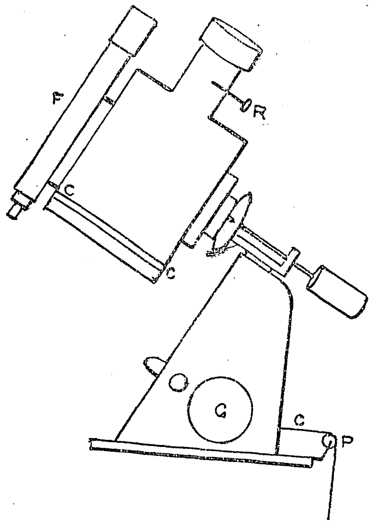
A Fellow of the Royal Astronomical Society.

STELLAR PHOTOGRAPHY—THE LIVERPOOL ASTRONOMICAL SOCIETY'S RESEARCH—DESCRIPTION OF THE STELLAR CAMERA: HOW THE PHOTOS. WERE TAKEN AND REDUCED — EFFECT OF COLOUR — VARYING EXPOSURES.

[26757.]—PERHAPS "F.R.A.S." will allow me to supplement his remarks in letter 61355, p. 420, by giving some account of the research on stellar photography undertaken by me for the "L.A.S." By the time this letter appears I trust that the results will be printed and obtainable by those of "ours" who wish to have them. Lack of funds has put an end to the research, and it must be left to the Americans to carry it out. At the present time Prof. E. C. Pickering, by the generosity of his fellow-countrymen, is doing the same work, and using the same method.

The camera, which was placed at our disposal by Mr. Howard Grubb, was fitted with a lens (compound) of 4½in. aperture. The lens is fitted with the ordinary rack motion for focussing (R, Fig. 1); but in case any of your readers should think of carrying on the work, I wish to point out that the rack-work should be of the strongest kind, as I found the lens liable to slip. Further, the lens should have a greater focal length: ours had only a focal length of a little less than 16in.; consequently, the distortion on any but quarter plates was serious, enlarging the discs of the stars, and so losing the fainter ones. In front of the lens was a wooden cap fitted with cloth, which could be taken off at pleasure. Here, too, I would suggest that the cap might be a simple piece of metal placed in such a way as to rotate at the side of the lens, so covering or uncovering without any actual contact. The accompanying rough drawing will show the position

FIG. 1.

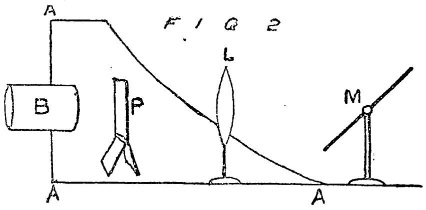


of the finder. This is somewhat in excess of the focal length of the photo. lens. The finder is fixed to the camera in the usual manner. After several arrangements of wires, I found that a simple cross wire worked best, and if a star is placed slightly out of focus and brought behind the wire, it can be followed better than in any other way, as the slightest clock error is shown by the star disc being no longer equally divided by the wire. A fairly high power should be used. The camera is cut from C to C, to allow the plate carrier to be introduced. The plate is introduced into the carrier at the back, and held firmly by a spring, thus preventing slipping, and robbing the L.A.S. of the honour of discovering planetoids in the Orion Nebula. The equatorial stand was of iron. The polar axis turned in V bearings. The iron stand was backed by a thick hollow stand of wood. In this stand, and thus out of the way of any accident, was the clock. The only part appearing on the outside was the large gearing wheel G, working the endless screw which turns the polar axis by means of a smaller wheel. At the back of the stand the cord C carrying the weights came out, and passing over a pulley, P, went down into a wooden box sunk 6ft. into the ground. The stand was fitted with slow motions in R.A. and Decl., and with hour and declination circles.

Let us now proceed to the actual working with the instrument. Throughout the work Wratten and Wainwright's "drop-shutter" plates were used. Other plates were tried, but these were found to give the most satisfactory results. The pyro. developer was tried, but soon gave place to the ferrous oxalate. The latter was obtained by making saturated solutions of ferrous sulphate and oxalate of potassium (neutral). To insure the best action, these solutions were made fresh for each evening. The oxalate of potassium solution was then held up to the light, and the ferrous sulphate added drop by drop till no more could be added. For developing a small outhouse was used. The plate was taken out of the carrier, placed in running water, and then plunged into the developer, care being taken to immerse the whole plate at once. It is a most interesting sight to see star after star come out as a black dot on the white plate. The development was continued till the plate changed from white to grey. The negative was then washed and fixed with hypo. in the usual manner.

Apart from the interest of having a record of the state of the heavens free from all possibilities of error—a record, as it were, self-written—the plates suggested an altogether new line of research—viz., the comparison of actinic magnitudes with those determined by the eye. Here, then, there opened out an entirely new method of photometry—one-sided, indeed, since the record was only of the violet rays of the spectrum, but valuable from the permanency of those records. The question next arose, How can the magnitudes be obtained from the plates? For reasons set forth in the "Catalogue of the Magnitudes of 500 Stars determined by Photography," the stars were made to come out as lines instead of dots, and this method has been adopted by Professor Pickering. Indeed, it seems the only one which nullifies at once all errors due to partial faults in the plate and local mistiness in the sky, &c., while it affords the great advantage of comparing lines together instead of points. Sarting with no previously-beaten track before us, the "solvitur ambulando" was converted not infrequently into "solvitur cadendo." How were we to form a scale? How reduce plate after plate? Such and many other questions were before us. Mr. W. L. Stubbs and myself took a plate, and having fixed upon the brightest and the faintest marking, we called the first 100 and the last 0. We then proceeded independently to assign numbers for the impressions of the rest of the stars. Our results agreed admirably. Then from the D. M. the magnitudes of the stars were taken, and we at once found that it was quite easy to obtain a value which would reduce the stars on the photograph to magnitudes which corresponded in the majority of cases with those in Argelander. The disagreement of the remaining stars was due either to an error in the eye magnitude, or to an abnormal condition of the violet rays in the stars.

Fig. 2 gives a rough idea of the apparatus used



for reducing the magnitudes. The light is reflected from a mirror, M, movable in all directions, and is concentrated by a large lens, L, on the plate P. The plate is viewed through two powerful lenses mounted in a tube B, and fitted with rackwork for focussing. The tube and plate are contained in a box A A A, which shields the plate from all side lights, and the eye from all direct light. If the plate is too transparent a thin piece of paper is placed immediately behind it. By the side of this apparatus was placed the "Atlas of the Northern Heavens," by Argelander; also a notebook, and the volume of the D. M. Certain stars having been selected as comparison stars, the rest of the plate was reduced, the stars being first identified in the atlas, then the photographic magnitude entered in the notebook, and lastly, the number and magnitude in the D.M. Before the work came to an end the first six hours of R.A. in zone + 40° had been photographed on twenty-nine plates, thus allowing the magnitude to be determined for the most part from two, and, in some cases, from three or four plates. Although the stars were allowed to come out as lines, all down to the eighth magnitude are on the plates, while from eighth to ninth nearly 70 per cent. are to be found.

A question that speedily arose from these results was this: Can we fix the star's colour by the difference between the photographic and eye magnitude? The difficulties in the way were considerable, for very little is known about star colours when we come to stars fainter than the sixth magnitude, and the stars above the sixth magnitude are liable to over-exposure on the plates. However, a general examination of every plate taken, not only in zone + 40°, but in other parts of the heavens, yielded the following mean results:—

A red star	decreases	2·5	mag.
An orange-red star...	„	1·9	„
An orange star	„	1·6	„
A yellow-orange star	„	1·3	„
A yellow star	„	0·8	„
A yellow-white star.	„	0·4	„
A white star neither decreases nor increases.			
A bluish-white star	increases	0·5	mag.
A blue star............	„	1·0	„

The largest decrease is in the star B 211 Cancri, which is reduced from 6·5 to 9·4.

Lastly, I must say a word or two as to an interesting attempt made by Mr. Stubbs and myself to determine the least magnitude photographed in a given series of times. To obtain trustworthy results, it was essential to have the same field of stars photographed upon the same plate the same night, the exposure differing each time. A camera with a lens 2½in. aperture was strapped on to the other end of the declination axis of the 17¼ equatorial. Immediately before the carrier was a large piece of cardboard, and in the centre a hole was carefully cut in such a way as to leave only one-fifth of the plate exposed at a time. The carrier was divided outside into five portions. The first division left the first fifth of the plate exposed. After the exposure the carrier was pushed down to the next division. By this means we

eliminated the causes of error, the field being the same, the plate being the same, the exposure alone altering. Several plates were thus taken with exposure of one, two, three minutes, &c., each new plate beginning with the last division of the previous one, and thereby securing an overlapping and continuous record. The stars in this case were allowed to come out as dots, being accurately followed. The great pressure of other work prevented our going into the question as thoroughly as we wished, but the results we obtained, such as they were, were plotted down, and a curve drawn, from which I take the following readings:—

Magnitude. Argelander.	Exposure required. m.	s.
5·0	0	1 ±
6·0		30 ±
7·0	1	15 ±
8·0	6	20 ±
8·5	60	0 ±

Plates taken with the 4½in., but which were not taken for this purpose, gave much the same result, the magnitudes being diminished by about 1·6 mag. Such, then, are some of the interesting results that have been obtained. They are, I think, very encouraging, and open out new fields of research. It is to be hoped that some sturdy English amateur may be found who in friendly rivalry will compete with the Americans. At present we have only a few star-picture makers, who seem incompetent to obtain any results except erroneous ones, while their pictures of nebulæ suggest that the author has sat in a pail of whiting, and then on a black piece of paper.

T. E. Espin.

Liverpool Astron. Society's Observatory, Wolsingham, Darlington, Jan. 21st.

66 CETI.

[26758.]—I AM sorry that, owing to the very unfavourable weather, I have been unable at present to examine 66 Ceti myself; but I hope the following results may be of interest to Mr. Dowsett (letter 26718, p. 451).

66 Ceti is included in Mr. Gore's "Catalogue of Suspected Variable Stars" (Gore, No. 58), on the authority of Taylor, who first seems to have suspected variation, and to have referred to the matter in the "Madras General Catalogue."

The magnitudes in Webb are taken from Smyth, who, as usual, assumed the magnitude of the principal star from Piazzi's second catalogue; the magnitudes in the "Star Guide" are, as I have stated in the preface, almost always taken, as in the case in question, from Dembowski's observations with the 7½in. at Gallarate.

Of 66 Ceti Gould says ("Uranometria Argentina," p. 313): "Taylor designated this star ('Gen. Cat.' 725) as a variable, but I find no evidence in support of this opinion other than the very slight discordance of the recorded values of the magnitude. D'Agelet twice noted it as 7, Lalande, as 6½ and 6; Piazzi, 7; Bessel, 6; Johnson 6·0. It is not in the "Uranometria Nova," and Heis makes it 6⅓. The Albany estimates in 1858 give 5·9; five Cordoba determinations in 1871 and 1874 vary only between 5·7 and 5·9." Gould gives 5·8 as the magnitude in the test, the magnitudes of the components being 6 and 8. Sir W. Herschel gives the magnitudes as "very unequal" on October 13th, 1782, which may indicate a difference of 1½ mags. between them. Piazzi gives 6 and 8 for the mags. of A and B of the pair in his first catalogue, and 7 and 9 in his second. However, as he gives the magnitude of such a star as *o* (Omicron) Cephei, for instance, as 7, though it is really about 5½, his estimations, made with a bright field illumination on a 3in. telescope, are not very trustworthy. Struve gave 6, 9 from four observations with the Dollond transit in the last two months of 1819; and H_2 and So 7, 8 "pretty unequal" on November 23rd, 1822. They remark that "the magnitudes, too, disagree with those of M. Struve (6 and 9)"; and, indeed, H_2 and So's 7 and 8 would probably mean 6½ and 7. Struve again found 6 and 8 with the 10ft. transit in 1821, and 6·2, 8·5 with the circle in 1822, 1823, 1824; while from the micrometrical observations with the 9½in. refractor, from 1829 to 1835, he found 6 and 7·8, the greatest difference being 5·5 and 8 in December, 1830, and the nearest approach to equality between the two components being registered in August, 1835, the magnitudes being respectively 6·5 and 7·5. Dembowski assigned 5·4, 7·5, as his estimates in 1854, the greatest difference being 4·8 and 7·0 in 1854, October 9th. Howe, at Cincinnati, gives 6·0, 8·0 as the result of one evening's observation in 1879, and Engelmann, at Leipzig, 5·6, 7·8 as the result of six evening's observations in 1882, 1883, and 1884. Houzeau gives 66 Ceti as a naked-eye star of the 6th magnitude in August, 1875; but it does not appear to have been photometrically measured by Messrs. Plummer and Jenkins, at Oxford. The Harvard photometrical measures make it 5·64 mag. Mr. Gore estimated it as 5·4 mag. on Nov. 21st, 1884. It seems to me that the *comes* may be slightly variable, and that this variation produces the slight change of light in A that seems to have been noticed by some observers with the maked eye or field-glasses. Both stars are animated by the same common proper motion, which amounts to 0·54″ annually. Though they have passed over nearly a minute of space since the time of Sir W. Herschel, no change seems to have occurred in their relative position angle or distances.

Jan. 24. **H. Sadler.**

A NOVEL FORM OF OBJECT-GLASS.

[26759.]—THE remarks of "our" valued contributor, "F.R.A.S.," in your issue of the 14th inst. will, I hope, draw the attention of practical opticians to the question, whether the errors of a large single lens, can be balanced by the opposite action of a small lens, placed not very distant from the focus of the large one. As regards Dr. Schott's new optical glass, I may say that soon after my query appeared in the "E.M.," some gentlemen very kindly sent me (through you, Sir) a copy of Schott's catalogue. It contains a long list of glasses of very varied character, and very different from any I have hitherto seen. I shall send the list to these columns as soon as I have the opportunity to copy it out, with the requisite explanatory remarks.

In connection with the subject of this letter, I may state that glass No. 1 on the list is a light phosphate crown index for the D ray 1·5159, and giving a difference of refraction between the C and F lines of ·00737. Thus it has a very low dispersive power, considerably less than the English hard crown. The last glass on the list is a flint of very great density, specific gravity 6·33; index of D ray 1·9626; difference of refraction for C and F lines ·04882. Its dispersive power is more than 3½ times that of the first-mentioned crown.

Suppose we take the common approximate formula for achromatising two separated lenses, which is

$$\delta = \frac{(F - s)^2}{F \cdot f}.$$

F being the focus of the positive crown lens, f that of the negative flint, s their distance apart, and δ the ratio of dispersive powers. Now let $s = (F - f)$ and our equation reduces to

$$\delta = \frac{f}{F}$$

which states that the combination will be achromatic when the foci are *inversely* as the dispersive powers. This is exactly the reverse of the condition for contact lenses; for if $s = 0$ in the above formula

$$\delta = \frac{F}{f}$$

which is the ordinary approximate rule.

Now let us inquire what will be the effect of the combination when s has the value $(F - f)$. Evidently a concave lens placed at its own focal length in front of the focus of another convex lens, will annul the positive refraction of the latter, and restore the rays to parallelism. The combination thus forms a simple Galilean telescope; and the reciprocal of the ratio of dispersive powers is the measure of the magnifying power. If the two preceding kinds of glass were used, this would be—

$$\frac{1}{\delta} = \frac{F}{f} = \frac{70}{19 \cdot 7} = 3 \cdot 55.$$

In this position the chromatic aberration would be balanced, and consequently, if the lens were drawn back so as to allow the rays to come to a positive focus, under-correction would result. Let us modify the first formula in order to find if this can be avoided. Instead of s being equal to $(F - f)$, put it $= (F - nf)$, n being a proper fraction. Then we have—

$$\delta = n^2 \frac{f}{F}; \text{ or } \frac{F}{f} = \frac{n^2}{\delta}.$$

If we assume the use of the foregoing glasses, we have (since $1/\delta = 3 \cdot 55$)—

$$\frac{F}{f} = 3 \cdot 55\, n^2.$$

And as n is a proper fraction, whatever value we may give to it will always make the ratio F/f less than 3·55; so that it would seem this is the maximum ratio of foci which can be used in such a combination.

This result is obvious from the fact that if the concave be placed so as to allow under-correction for the sake of obtaining a positive focus, an increase of chromatic negative error is required, which would also increase the negative refraction, and thus destroy the object sought to be attained.

In the course of these remarks I have used only simple approximate formulæ, and the results they give may not altogether be correct; but they are sufficient to convince me that if the new arrangement be perfect, I have much to learn and more to "unlearn."

So far we have considered the corrector as a simple lens; but suppose it to be a compound of crown and flint, will such a one answer the purpose? I believe to a *certain* extent it will; to *what* extent I cannot say.

The reduction in size of the dialyte correctors can no doubt be very considerable, but the limit must be practically determined. To use the ordinary formula of Rogers, which is—

$$f = F \cdot \frac{a^2}{A^2} \cdot \left(\frac{1}{\delta} - 1\right)$$

where f = focus of one corrector (the other of equal opposite focus) F = focus of o.g., a and A the acting semiapertures of corrector and o.g. Suppose the glasses to be the same as above-mentioned, then—

$$f = 2 \cdot 55\, F \cdot \frac{a^2}{A^2}.$$

Let us assume that the aperture of the correctors is $\frac{1}{10}$th that of the o.g., then—

$$f = \cdot 0255\, F;$$

or if F be 100, then $f = 2 \cdot 55$; that is, supposing a single o.g. (crown glass) of 10in. aperture and 100in. focus, it is theoretically achromatised by two crown and flint lenses, each of 2·55in. focus (positive and negative), and 1in. aperture, placed about 10in. in front of the focus of the o.g. I wonder if theory is borne out by practice; I feel rather doubtful. Will our friend "Prismatique" and others say a few words?

In connection with this matter, may I ask "F.R.A.S." if any explanation has been given of the discrepancy between the theoretical star-discs calculated by Airy's undulatory theory, and those measured in practice;—and perhaps also Mr. Sadler, who kindly referred me to M. André's theory, will say if this physicist gives any definite rule or formula for calculating such star-discs, and in what respect it differs from Airy's.

Orderic Vital.

HORIZONTAL WIND POWER.

[26760.]—IN reply to several correspondents in regard to the above, I am unable to refer to Vol. X. In regard to Mr. Raymond Browne's remarks, I am perfectly aware of the many uses to which windmills may be applied, the chief of which, I believe, to be the raising of water, for which purpose, no doubt, intermittent power may answer. There is a 10ft. American mill erected near my house, which pumps sufficient water into elevated tanks to suffice for the watering of a large garden, and the value of such windmills only requires to be more widely known to insure a large demand for them.

Replying to "Gwalia," I was precisely of his opinion till I took out extracts from our local meteorological reports, when I (reluctantly) came to the conclusion previously stated. I thought that one of the 14ft. windmills, shown at Colonial Exhibition, and which were stated to give 2H.P. with 18 miles of wind, would, at any rate, give 1H.P. for twelve hours out of the twenty-four. From the table below, if the Editor will be good enough to print it, as it may prove of some interest in this discussion, it will be seen that the least recorded speed of wind during the 17 weeks was less than one mile per hour; that there were 13 days less than four miles, and 17 under six miles. Even in the week when the speed was greatest, there was one day when it was less than 5½ miles. It must, of course, be borne in mind that, for the purpose of electric lighting, a dynamo must run at not less than a certain speed, and until that speed was attained by the windmill, it would have to be cut out of circuit: otherwise the accumulators would discharge themselves through the dynamo. There seems, therefore, to be considerable difficulty as to the practical application of windmills for electric-lighting purposes. Of course I am referring to such mills as might be erected near one's dwelling without being an eyesore to the neighbourhood.

A friend who is agent for the sale of an American windmill has recently returned from America, and told me what I stated before in regard to the ideas of the ingenious people over on the other side. By the way, Mr. Vallance is mistaken as to a seven-mile wind being ⅗lb. per foot. I think authorities (Molesworth, &c.) state that 10 miles is only ½lb., so that no doubt his calculations of power will be materially altered.

I cannot state what is the speed of the wind in other places than this; but I waited on Mr. Joseph Baxendell, F.R.S., F.R.A.S., who is responsible for the returns here, and he informed me that some time ago, having charge of similar returns for the Manchester Corporation, he had an anemometer in use at Anfield (one of the waterworks stations), which showed a less wind speed (some two to three miles per hour) there than here, though the elevation, of course, is much greater. Mr. Baxendell has since kindly brought me a table showing the mean daily movement of the wind at Southport, from 1872 to 1886; which shows that in the former year it was 311·4 miles, and in the latter 187·1

miles only. How far this may arise through houses being built round the park in which the observatory is situated, I cannot say. I have obtained from Mr. Hartnup, of the Liverpool Observatory on Bidston-hill, results from 1879 to 1883; but as these are daily records, it will take some time to arrive at the mean for the several years; this I will get out and see what difference there is between the two places.

It may be well to note that on the open sea 650 daily observations, taken on cruise of *Challenger*, gave a mean hourly velocity of $17\frac{1}{2}$ miles, whereas 552 observations near land, gave $12\frac{1}{2}$ miles only. At Valentia, Ireland, one of the windiest situations in western Europe, three summer months of '78 gave a mean hourly velocity of 13·3 miles, the minimum 10 to 11 miles, from 9 p.m. to 6 a.m., and maximum exceeding 16 miles, from 11 a.m. to 5 p.m.—("*Meteorology*," *Ency. Brit.*, 9th edition.)

The 17 weeks in the table are not quite consecutive, simply because I failed to find all the reports in the local papers in our newsroom. The anemometer is about 60ft. above the mean sea level.

VELOCITY OF WIND IN MILES, SOUTHPORT.

Southport. **Benjamin Boothroyd.**

HORIZONTAL WINDMILL.

[26761.]—I NOTE that in P. Vallance's account of trials with a vertical against his horizontal windmill, that it would seem from this description that the hauling rope was common to both, and, therefore, that that machine which had sails upon it had also, besides doing its legitimate work, to keep the other mill (without its sails) also in a state of revolution. If this were the case, it is obvious that the weighty concern would have a great advantage over the light-weighted opponent; also he does not state whether the vertical, which would run so much faster than a horizontal, was so geared as to make the speed of the ploughs equal in both cases. I feel curious to know "at what part of the revolution, and for what length of time" a more effective surface can be obtained, or even a larger effective area of sail in a horizontal than in a vertical. I also note that he is silent as to the weight and cost of all the metallic parts, which would, I opine, form an important item. **A., Liverpool.**

[26762.]—SEEING the controversy now going on, and being interested in a wind motor for compressing air, I should like your advice as to which is really the best or most powerful. As to the horizontal ones I do not quite understand their action, or how the wind acts on them without their being sheltered on one side from the wind. I have a very light waterwheel made with zinc rim and buckets. Could this be used in any way for a wind motor by, say, concentrating the wind on just one half, and sheltering rest of it? The wheel is 3ft. diameter, with 1ft. wide buckets, 4in. deep. I am situated just now where there is no block for the wind for miles, and when it blows, I get the full force of it. **L. W. D.**

PATENTS AND LAND.

[26763.]—UNDER the heading "Patents and Land" in yours is a letter from our old friend Thomas Moy, than whom no one is better competent to speak about patents and inventions, but whose violent prejudices on the subject of land and landlords spoil the effect of his argument. The subject of inventions and patents is of deep interest to many of your readers, and I hope to be excused in making a few remarks on the subject of Mr. Moy's letter.

The land question is to Mr. Moy what King Charles' head was to one of Dickens's characters—he can't keep it out of his kite. In the case he puts of a landlord reclaiming land from the sea, the landlord *does* create a new combination, a new and useful one too, and, moreover, one that probably lasts for ever after, whilst a patented invention for 14 years is frequently as long as a patent is worth anything—new methods and combinations having superseded the original.

But take the case of a leaseholder of a mine who has it for a short term, and after spending £20,000 may or may not "strike oil," and when he does must pay royalties and taxes, &c. Skill and money have to be employed, and risk taken in either case, and Mr. Moy might find patenting inventions more profitable than either of the above operations.

The inventor, however, has a good case on the merits. Let us compare him with an author: the latter "invents" a book, and for the trifle of five shillings obtains registration of it, and a copyright or monopoly for 42 years. The patentee invents a machine and obtains a monopoly for 14 years only, and the Government exacts from him £154—from the author, nothing at all.

Both on the ground of shortness of term allowed for his invention to fructify and the heavy fees payable, the patentee is unjustly used by the Government. Although 17,000 people chose last year to enter into this bargain with the Government, it does not alter the case. By taking these heavy fees the country is deprived of hundreds of good inventions, which would bring wealth and find employment to many more than at present. Granted the fees are only £4 for the first four years, yet anyone taking up an invention must do so with all these heavy payments in prospect, and numbers of useful inventions come to an untimely end in consequence. The United States are wiser, taking only a few pounds, comparatively, in the first instance and have done with it, granting a patent for 17 years. The States find their account in it by the impetus given to internal trade and manufactures through the inventive faculties of their people being fostered and encouraged, while our system acts in restraint of trade.

I maintain that inventors should be encouraged in every way to bring out new ideas and combinations; should be charged only a few pounds for examining, printing, and registering their patents; we should then be able to hold our own against Germany and the States both; for English mechanics are clever and reflective, and the country would benefit immensely more by extension of trade and manufacturing industries than it ever can by the imposition of high fees on patented inventions. **O. G. Beard.**

NON-FLESH DIET AND HARD WORK.

[26764.]—IT is a great pity that Dr. Allinson, "The Lydney Dispenser," and other enthusiasts cannot be induced to know that all the units of the human race are not exactly alike. Hobbies are all very well in their way, but they get spoiled if they are ridden to death. It stands to reason that men who have been brought up from infancy on oatmeal and teetotalism should do more work on that particular diet. It is part and parcel of their mode of living, and any sudden change of diet would probably upset them in common with other people. Dr. Allinson should also know that it is perfectly absurd for any man or body of men to do hard or heavy work on a full or overloaded stomach. A heavy meal should be taken after work is over (as did the Highlanders); if a heavy meal is necessary at all, and if those Scotchmen had started on a stomach full of oatmeal they would have done as little work as the Englishmen. All this is a matter of personal experience with me, and I can do as much work on one kind of food as another; but I must first get thoroughly accustomed to the change. As a rule I eat no meat, but content myself with fish, and very little of it. Personally, I think that nineteen people out of twenty not only eat too much meat, but too much altogether. I know that at one period of my life I was perfectly incapable of doing anything after a two o'clock dinner. I am now as fresh after dinner as I was before. I did not consider myself a large eater, and don't suppose I ate on the average more than anyone else, and I do not now eat more than half or one-third of what I used to do, and of a much lighter kind of food.

A man who has been used to meat craves for it in much the same way as a drunkard craves for drink. At some workhouses where fish dinners were tried the inmates said they felt as if they had had no dinner at all, and this will be the case with anyone else; but perseverance for a few days or weeks soon relieves that feeling. A friend of mine once, to the surprise of himself and everyone else, won the first prize at a shooting match, and he attributed it to the fact that all the best shots had a heavy luncheon just before; he had none.

I am not a vegetarian; but I take a little animal food, because I feel I cannot do without it. I am not a total abstainer, but I hardly ever touch alcoholic drinks, as I don't think they are good for me; but I don't wish to lay down hard and fast rules for everyone else. Many people live to eighty and ninety years of age on a good supply of meat and alcohol, and many people kill themselves with the same.

The leading idea should be to be temperate in all things, avoid bigotry in every shape and form, and don't imagine that your coat is made to fit everyone else. **Os.**

DOES THE SUN PUT OUT THE FIRE?

[26765.]—"K. E." (letter 26745, p. 454) asserts as a fact that which is disputed by almost everyone who has studied the subject. I am glad, however, to find that he limits the sun's supposed influence in this direction to cases where the fire has been neglected and allowed to get dull, which, I take it, will often be followed by its completely dying out, either with or without the sun's special assistance in doing so. "K. E." goes on to say that in the case supposed the draught ceases, and the fire consequently goes out because the sun's rays warm and rarefy the air of the room as much as the fire warms the air passing over it up the chimney. Does "K. E." wish us to understand from this that the air of the room is only partially warmed by the sun, a special reserve of cold air being left unaffected for the fire alone to act upon? Otherwise, supposing the air of the room to be generally warmed by the sun's direct rays and the ordinary currents that would be set up, which I maintain would be the case, his argument has no foundation, as the action of even a dull fire would always have a tendency, under such circumstances, to create a draught.

I am inclined to believe that the tendency of the sun to dull or put out a fire is strictly limited to its apparent effect in doing this, and that when Jane, after neglecting her fire too long, gives it a gentle stir, draws down the blinds, and soon begins to discover a few red-hot patches which previously appeared to be black, her traditional instincts at once assure her that the fire is beginning to "draw up" because she has shut out the baleful influence of the sun. **W. T. N.**

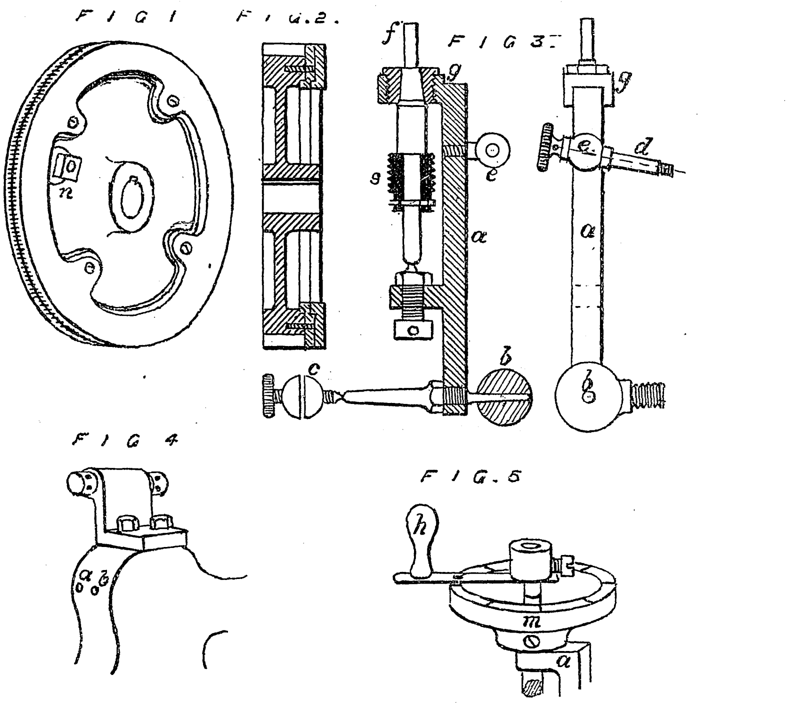
SUGGESTION FOR A SAFETY PARAFFIN LAMP.

[26766.]—ACCORDING to my design, the lamp is to be without having any bowl, so that consequently there could be no explosion of a bowl. My suggestion is that the reservoir for the oil be formed of a coil of metallic tubing, capable in itself of holding a sufficient quantity of oil. One end of the coil would open into a wick-chamber in the centre; the other end would be closed with a screw-stopper having a vent. In case of the upsetting or falling of the lamp, a small quantity only of the oil could be spilled, particularly if regard were paid to this object in the manner of coiling, and, at the same time, there would be no brittle substances like bowls to be broken by the fall. I should suppose that a lamp constructed on this plan would be absolutely incapable of exploding, assuming that the bore of the tubing were sufficiently small. The interposition of so much metallic material among the oil ought to be effectual in preventing explosion, as it is a well-known fact that the intervention of substances, such as powdered glass, sand, &c., will effectually destroy its explosive power. **E. H.**

ROAD REFORM.

[26767.]—THE great question for the country to decide respecting the reform of our common highways is, "Will it pay?" Let us compare the work to be done, with and without reform. For physical work means "expense," whether paid for directly or indirectly, because it means "consumption." If "F.R.A.S." is afraid that in reforming our roads we should cut through park or farm (though country roads generally run through farms) in order to avoid unnecessary road-hills, suppose we reform without altering present positions of roads; then there are hundreds of hills and valleys to be levelled. Will it pay to level a road that has an average daily traffic of, say, 20 tons along it—this means 7,300 tons yearly? This road may have a succession of hills and valleys along its course, let us say five hills and four vales, each hill averaging fifteen yards in altitude; then the yearly work caused by these five hills is 7,300 tons multiplied into 225ft., which equals 1,642,500 tons to be raised one foot annually at public expense; without taking lost time, fatigue, and extra distance into account. Surely it is cowardly to say with "F.R.A.S."—"There the road is, we can only make its surface firm."

Now let us reform this road by levelling it—i.e., by taking off the tops of these hills, and casting them into the vales; then all the earth taken from these hill-tops has simply to be tipped downwards, not raised from the vales to the hill-tops, as our traffic has to be raised. Then, again, the weight of earth taken from the hill-tops has to be shifted but once, whereas the 7,300 tons of traffic has to be raised to the tops of the hills every year. Ten yards taken from a hill-top may raise a vale ten yards; then public traffic gets the double advantage of twenty yards, or 60ft. Then, probably,



the load that now requires four horses will require but two.

I may inform "F.R.A.S." that I am not prepared to pay more road rates, though reform should take place, but rather less; for at the present time if I want a ton of coals brought from the nearest station (seven miles) I must pay a sovereign for them. The coals are 9s. per ton at the station, and yet my house is on a plane with the station; but there are 750ft. to be climbed in the several hills that lay between my house and the station.

The question of road reform is not a parochial but a national one. All our public roads are under the care and protection of the Government. It is the province of the parish simply to repair the surface of its roads for the use of them. The prerogative of real reformation belongs to the Government. Being thus a national question, the work of road reform may be accomplished in a few years; but the entire payments for that work need not be finished for thirty, fifty, or a hundred years.

Norfolk.

DIVIDING APPARATUS.

[26768.]—I THINK your readers may care to see an arrangement I have just finished for dividing for wheel-cutting, &c. I hope, too, it may lead others to send us some account of the work they have done lately.

Mine is a 5in. slide lathe by Milnes. I have also a small $3\frac{1}{2}$in. lathe, which I find very useful for small work, and to save removing and clearing the other in the middle of a job, when a screw or bit of drilling is required. The pulley of the larger lathe was fitted with a brass division plate, having three rows of 180, 144, and 96 holes. This I had taken off, and in its place was fitted a worm-wheel, 7in. diameter, and $\frac{5}{8}$in. thick, divided into about 240 teeth, which teeth come just about 11 to the inch, and so suit the $\frac{5}{8}$ Whitworth thread. The worm-wheel is made as two plates with a circular fitting, and the two halves meet at the middle of the teeth, and are secured to each other by four screws passing through four lugs in the plates, Figs. 1 and 2. This was to enable the two halves to be turned on each other; the screw holes should be rather large to enable the teeth to be adjusted to one another. The number of lugs must, of course, be a divisor of the number of teeth in the worm-wheel. The plate came to me cut in the usual way, but on turning the front part half-round, there appeared inequalities in the correspondence of the teeth, which might amount to $\frac{1}{30}$in. A brass frame was then made (*a*) Fig. 3, and fitted into the ball (*b*, *b*) which takes the index spring; a second screw (*c*) was fixed into sole of headstock, to keep all firm below, and a screw (*d*) with milled head, passing through a ball attached to top of frame (*e*, *e*) was provided, which screw takes into a tapped hole in the headstock near the little hole for point of screw of oval-chuck ring. By turning head of screw *d*, the worm (*s*) is brought up into contact with worm-wheel. When screw *d* is released, frame can be turned down, and when screw *c* is taken out with a screwdriver, the whole frame can be removed, leaving no trace but the two small $\frac{1}{4}$in. tapped holes for *d* and *c*.

To complete the cutting of the worm-wheel, a second screw (*s*) was made, and this was filed like a hub with spiral groves, and hardened; a pulley was fitted on the top of the worm spindle at *f*, and the worm-wheel was then recut in several positions. The front of the worm-wheel was then bored as a division plate, and this will illustrate the use of the apparatus. There were four rows of holes: the first (diameter $6\frac{5}{8}$) contains the numbers 11, 13, 14 and 6, all in one row; 6 was added to save the other rows; 17 and 19 would have clashed, as the holes are rather large. The next row contains 192 holes in a diameter of $6\frac{1}{4}$in.; then come 120 holes in a diameter of $5\frac{7}{8}$, and then 72 large holes which are large enough for segment stops. The holes start from zero marks struck on the plate with the index point. The index point, like the holes, is made to an angle of about 18°, and the point rounded and smoothed, so as not to scratch the plate, as advised by "J. K. P." in back vols.; it has also a short shoulder which fits the larger holes, as these contain multiples of nine, and thus they are useful with the index peg as well as for the segment stops. The stop for these is shown at Fig. 4, fixed on top of the headstock; *a* is the tapped hole for the screw *d*, Fig. 3, and *b* is the counter sunk hole for oval chuck. All the divisions named, which contain every number up to 17, were produced from the 240 worm-wheel, which becomes almost a calculating machine. On the top of the frame at *g*, Fig. 3, will be seen a circular fitting which is true with the worm spindle; on to this was firmly fitted a 3in. wooden collar having circles scribed on it in the lathe. These circles were then divided by the dividers into 4, 7, 11, 13; then on the top of *f* was fitted a small spring crank with handle, which could be brought up accurately to the marks, so as to give two turns (for 120), or $1\frac{1}{4}$ turn (for 192), $18\frac{6}{13}$ turns for 13 divisions, &c. You have simply to divide 240 by the number of divisions you require, and that gives the turns you give the worm-screw between each cut. For example: required 192 holes, $\frac{240}{192} = 1\frac{1}{4}$ turn. I have now in hand some brass collars (see Fig. 5,) which will be divided on the top edge for a little tooth or knob in the spring crank to take into; *h* is handle, *k* the knob, *m* the brass collar, *a* the top of the frame. Had the segment apparatus and worm-wheel been placed behind the pulley as usual, the lock nut *n*, Fig. 1, would have intervened, and if it had been at all loose, all accuracy would have been lost. My few patterns are with Mr. Milnes, and anyone may have castings from them.

F. A. M.

CUTTER BARS, &c.

[26769.]—AS a continuation of letter 26584, will you permit me the following?

Your correspondent "H. O., Glasgow," very kindly forwarded me three pieces of Mushet's steel, which I have used with heavy, and also with light cuts, and at such a speed that made the cutter smoke; under these extra strains it has stood admirably, and I have formed a good opinion of it for all kinds of metal turning.

Can any of "ours" tell your readers its composition? and alongside of it, place the composition of the very best crucible cast-steel, so that readers may study the difference?

I was pleased on opening the magazine yesterday to find the "Willis Haydon Tool-holder" sketched as an advertisement, and hope that every lathe-man will make, or purchase, one that sees it. With this holder and a $\frac{3}{8}$ square rod of Mushet's steel every amateur and every professional turner is equipped for all outside turning. A word of warning is necessary to users of this steel to never put it in water while hot, but after it is forged lay it down to cool. There does not seem any means of filing this steel, but by the aid of an emery stone, a good many shapes of cutters may be formed direct from the rod. When it is hammered it should be fully as hot as crucible steel is made when forged, and by no means hammer it when getting cool.

Jan. 22. **Evod.**

LATHE MATTERS.

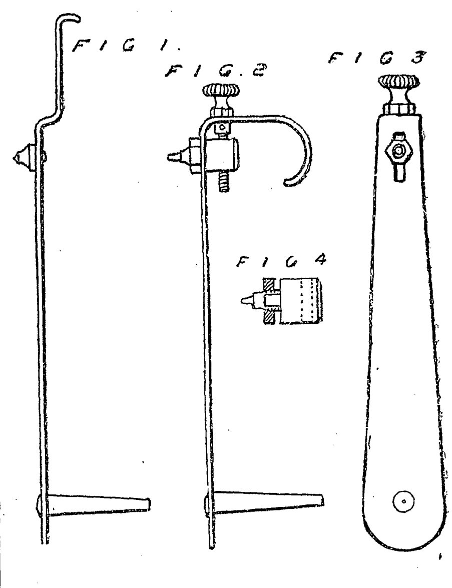
[26770.]—OH, "Vulcan," how could you apply the epithet *thirsty* to such an ardent teetotaller as "F.A.M."? *Hungry* I am for all I can learn about lathes and tools, and send my small contributions in hopes of drawing others to help me. Mr. Jesse Lowe, for instance, could tell us many things about his medallion machine, and other original tools, three-mandrel lathes, and such like.

I do not know where to go for information on the subject, though I believe it is contained in the late Mr. Hartley's unpublished book. Two hundred subscribers for this have sent in their names, and probably the reception of 50 or 100 more would justify its publication.

"W.A.S.B." would find, in Holtzapffel's Vol. IV., some fine patterns of plain turned work, and if he likes to writes to me at 4, Clarence-road, Tunbridge Wells, I will tell him of another source from which he may draw.

As regards A. Gray's question *re* the Edmunds mandrel, I should be well satisfied to adopt it; if I changed anything, it would be to substitute a Whitworth thread for the special thread advocated.

I send the inclosed sketches to show how easily



the plain index, Fig. 1, was altered to the adjustable index, Figs. 2, 3, 4, this being the index used with the division-plate described in my last letter. It may not be perfect, but it is very simple. The old index point was removed, and the top of the spring heated and bent round as seen, the oblong slot filed, the new peg with its nut, Fig. 4, made to fit the coned holes, there being a very short shouldered fitting to go into the larger holes for the segment stops; the adjusting screw completed the work.

F. A. M.

DETERMINATION OF SUGAR IN DIABETIC URINE BY PAVY'S AMMONIACAL CUPRIC SOLUTION.

[26771.]—IN response to the request of "M. O. H." (letter 26633), I now fulfil my promise to give working particulars of the admirable process introduced by Dr. F. W. Pavy, F.R.S.

The *solution* is made by taking—cupric sulphate 4·158 grammes, Rochelle salt 20·400 grammes, potash (caustic) 20·400 grammes, ammonia (sp. gr. 880) 300cc., and making these up to 1 litre; 10cc. of this are equivalent to ·005 gramme of glucose; or, 120cc. of the ordinary Fehling solution, with the addition of 10 grammes of potash and 300cc. of ammonia, may be made up to 1 litre, to form the same fluid. This is one-tenth of the strength of ordinary Fehling solution.

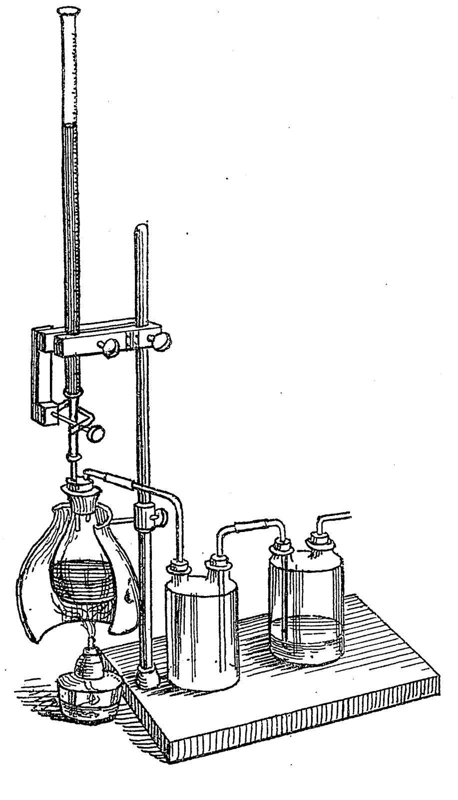
The *apparatus* of the most improved form is that figured here. It consists of a burette, from which is pendent by a short indiarubber tube, a flask of about 150cc. capacity. Flasks known as "carbonic acid flasks" answer capitally. The cork used is of

indiarubber, with two perforations; into one of these fits a short glass tube, connected with the burette by the piece of tubing mentioned above, and dipping a short way into the flask, where it is drawn out to a moderately fine point. The other perforation is fitted with a tube leading off to two Woulffe's bottles, one of which is about one-third filled with water.

The tube between the flask and burette is best compressed by the specially devised screw-tap figured. The ordinary spring-clip brings the fingers too close to the flame to be pleasant; nor does it allow so regular a succession of drops to fall. Behind the flask, to form a white background, is arranged the half of one of the ordinary white, opal gas-globes.

The *process* is as follows:—A preliminary test is made to see if the urine contains sugar at all. This cannot be made by the ammoniated cupric solution, since it is too delicate for that purpose. Into a test-tube place about 5cc. of the suspected urine, and about 3cc. of Fehling solution; boil the mixture for a minute or two. If the blue colour is destroyed and a red precipitate is produced, sugar is present.

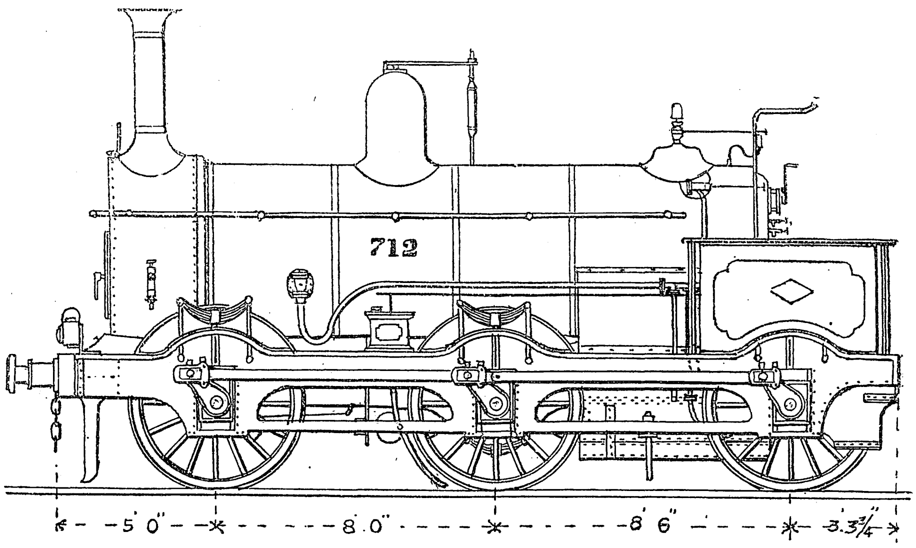
Now, dilute some of the urine to twenty times its volume, fill the burette with this, taking



care that the indiarubber tube and its jet are full too. Into the flask place 20cc. of the dark blue ammoniated cupric solution; attach it to the burette. Light the spirit-lamp or Bunsen burner below. Directly the blue liquid begins to boil, let a rapid succession of drops fall from the burette into it by turning the screw-tap. As the blue colour begins to fade, let the diluted urine flow into it more and more slowly, till the liquid in the flask becomes perfectly colourless. Take care not to let any more run in after the colour disappears. One or two trials will soon show whether you have stopped at the right time. Read off the number of cc. emptied from the burette. The liquid in the flask should now be perfectly colourless and free from any red or other deposit. If an unusually long time has been taken, a red precipitate of oxide of copper will come down, and the experiment must be repeated more rapidly.

The object of the Woulffe's bottles is to absorb the ammonia given off; but little will pass out of the second bottle, and this may, by an indiarubber pipe, be conveyed out of the window or down a sink. The ammonia condensed may be used over again.

Calculation of Results—Suppose 8cc. of the diluted urine decoloured the 20cc. of blue test liquid, and that if all of the urine had been diluted it would have measured 1,000cc. Then, since 20cc. of the blue liquid equal ·01 glucose and 8cc. of the diluted urine equal this 20cc., we have $\frac{\cdot 01 \times 1000}{8} = 1{\cdot}25$, or the whole quantity of urine contains 1·25 gramme of glucose. Urines containing very large quantities of sugar had best be diluted to 40 times their volume. Urines containing very minute quantities of sugar need no dilution.



Interfering Substances.—It is not necessary to precipitate the albumen, phosphates, &c., as in the Fehling method: they do not interfere with the accurate working of this method.

Alkaline tartrates and carbonates, when present, do not "gravely affect the accuracy of the indications," as mistakenly asserted by Mr. Allen from results obtained by Mr. Hehner with quite a different test fluid. Of course, if you vary the constitution of the test liquid, you will also vary the results: this is true also of every other standard solution.

The substances natural to urine that do interfere with the test, causing an over-estimation of sugar, are uric acid and creatinine. The first of these may not only be allowed for, but also be quantitatively estimated by the same test liquid, as was shown by Dr. Pavy in a paper in the *Medico - Chirurgical Transactions*, Vol. LXIII. p. 322. How, I shall be happy to show, if of interest to your readers.

The other substance, creatinine, according to Dr. G. Johnson, F.R.S., in a paper to the *British Medical Journal*, Jan. 8th, 1887, may also be eliminated. The substances equally interfere with the ordinary Fehling solution. They do not, however, seriously affect the *comparative* determination of sugar in urine.

Theory of the process.—This is not definitely settled as yet: all we know is that the boiling caustic potash breaks up the sugar molecules so that they may convert the cupric sulphate into sub-oxide. This sub-oxide would deposit as a red powder were it not for the presence of ammonia, which keeps it in solution. Hence, the reaction with this fluid goes on in an atmosphere of ammonia. If all the ammonia is dissipated, through too slow a titration, the oxide will deposit and spoil the reaction.

Advantages.—The fluid, once made, will keep for an indefinite time; the end of the reaction is sharply marked; there are no muddy red particles floating in a more or less blue liquid to be looked at through a cloud of steam, as in the ordinary Fehling volumetric method; no previous treatment of the urine is needed; it is more speedy, delicate, and accurate than the ordinary methods used. **Alf. W. Stokes, F.C.S.**

Vestry Hall, Paddington-green, W.

BURNT AIR.

[26772.]—IN connection with the warming of the interiors of buildings, we often hear of the injurious effect of burning the air by allowing it to come in contact with surfaces overheated, but not, of course, in combustion; more especially is the injury said to be caused when the overheated surface is of iron. What is the operation of this burning, and what is the explanation of the cause of the injury which is done to the air? Merely to raise its temperature would not, one would imagine, alter its constitution. One explanation is that the evil arises from the decomposition by burning of the dust floating in the air. But although this is generally accepted in the absence of some better theory, it appears to be scarcely sufficient.

Air consists of a mechanical mixture of the gases nitrogen and oxygen with a small quantity of carbonic acid (i.e., carbon and oxygen in chemical combination CO). May it not be that at high temperatures the carbonic acid decomposes and reforms with a larger quantity of oxygen, forming CO_2. or carbonic oxide, thus permeating the air with a more poisonous gas, at the same time robbing it of a portion of its free oxygen?

If neither this theory nor the dust theory be sufficient, does anything proceed from the iron or other overheated surface which poisons the air? **Wm. Archdeacon.**

MIDLAND GOODS ENGINES 700 CLASS.

[26773.]—I NOW beg to forward a drawing I made at Leicester Locomotive Department, 1869, of Midland goods engine No. 712, trusting it will furnish the information for which "Rover," page 442, asks.

The engine illustrated is one of those designed by the late Mr. Kirtley, and constructed by Messrs. Dübs and Co., 1869; the tender being of the same dimensions and weight as the one illustrated on page 412.

Diameter of cylinders	17in.
Length of stroke	24in.
Diameter of wheels..................	5ft. 2in.

The tractive force for each pound of effective pressure on the pistons being, therefore—

$$\frac{17 \times 17 \times 24}{62} = 111{\cdot}870\text{lb}.$$

Heating surface of firebox	103 sq. ft.
Heating surface of 168 tubes ...	993 sq. ft.
Total heating surface...	1,096 sq. ft.
Diameter of tubes outside ...	2in.
Area of firegrate	17 sq. ft.
Pressure of steam	140lb. per sq. in.

Weight in working order—	Tons.	Cwt.
On leading wheels	12	8
On driving wheels	12	13
On trailing wheels	9	12
Total	34	13

The "heating surface" above given is the amount as calculated from my own measurements; the weight was furnished to me by the designer.

Clement E. Stretton,
Consulting Engineer, Amalgamated Society of Railway Servants.
306, City-road, London, E.C., Jan. 21.

FAST TRAINS.

[26774.]—I DO not think that the G. S. and W. of Ireland Co. have any tenders nearly large enough to run without stopping from Dublin to Cork. No stop is mentioned in "Bradshaw," because passengers are not booked to or from any intermediate station. It is only on very rare occasions that the N.E. engines can run right through from Newcastle to Edinburgh—so one of the drivers told me last autumn. The longest run without taking water is made by the Mid. Leeds expresses, which often do not take water at Kettering. On the only occasion I have been in one of these trains—the 3.17 p.m. up from Nottingham—I particularly noticed that the driver took no water at Kettering, though it was rough, wet weather. It was not one of the very largest Mid. tenders; but much larger than any on the North Eastern.

I cannot at all see why it should be impossible for a large-wheeled single engine to attain a speed of over 80 miles per hour. I timed the Mid. Express just alluded to between Luton and St. Albans (10¼ miles), and it took as near as possible 8 min. between the upper ends of the two platforms. The engine No. 1568 has 6ft. 8in. coupled wheels, and 18 by 26in. cylinders, and if that kind of engine could attain a speed of nearly 77 miles per hour in heavy rain, over an undulating portion of the Midland, what is there to prevent the G.W. "Great Britains," attaining a far greater speed between, say, Swindon and Didcot, or Maidenhead and Westbourne Park?

It is quite a mistake to suppose that the "Great Britains," can only go down hill or on the level. I remember, one frosty morning in Nov. 1870, the Prometheus, which had been rebuilt a few

months previously, taking the 9.15 a.m. train from Paddington from Slough to Didcot (35 miles) in 37 minutes, nearly all slightly uphill. The train consisted of 12 old-fashioned B.G. six-wheeled coaches, and was well loaded, as it was a Saturday morning, and the trian took passengers for the Weymouth and South Wales sections, besides being the only good day train to below Plymouth.

Mr. C. Rous Marten seems to be unaware that most of the so-called "old single engines" mentioned in his letter (26651) have been quite recently rebuilt, and are to all intents and purposes, new engines. Probably the oldest single engines doing heavy work are some of the G.W. "Sir Daniel" class (378-387) which came out in 1866. I came with one of these (385) on Dec. 21 from Paddington to Swindon. The 41 miles from Reading to Swindon were easily run in 50 min. with a fairly heavy train (6.20 p.m. from Paddington), though the rails were very slippery from frost. The engine had brought up the 9.35 a.m. from Bristol to London. I know No. 385 and several others have not been rebuilt.

I cannot see why there should be any difficulty with G. W. No. 10 on sharp curves. She is not so long as the G. N. new 7ft. 6in. singles and cannot be longer than the "Great Britains," which have frequently run over the Gloster and Swindon and Maidenhead, Thames, and Oxford sections in days when those sections were B.G.

O. H. P. Scourfield.

EXPRESS TRAINS.—III.

[26775.]—

GREAT NORTHERN RAILWAY.

Grantham—King's Cross, 4.17 p.m. up. The best run, Nov. 24th, 1886.

Miles.	Stations.	Booked Time.	Actual Time.	Speed.
		p.m.	h. m. s.	
	Grantham	4.17	4 17 30	
29	Peterbro' (A) ...		4 52 0	$50\frac{10}{13}$

$17\frac{1}{4}$	Doncaster	4.37	4 42 30	46

REMARKS.—(A) Slack through Grantham; (B) Slack through Retford.

Load equal to 8. Loco. 707. Dimensions:—Cylinders, $17\frac{1}{2}$ by 26; coupled wheels, 6ft. $7\frac{1}{2}$in.; leading wheels, 4ft.; heating surface, 1,050 square feet. Water in tender, 2,950 gallons. Coal, $3\frac{1}{2}$ tons. Consumption of coal per mile, $29\frac{1}{2}$lb.

French Loco.

ELECTRIC LOCKING FOR RAILWAY SIGNALS.

[26776.]—IF Mr. Spagnoletti (page 452, 26727) will again read my letter, he will see that I do not oppose the system; but in line 5 I remarked, "but there is one most important and vital point which requires to be made clear." Now instead of explaining this matter, my letter is simply called "unpardonable" by Mr. Spagnoletti. He states he "admitted the point raised was an important one," and further that his system does exactly what I say it ought to do.

I am perfectly well aware that a long and somewhat strong discussion is taking place elsewhere between Mr. Spagnoletti and Messrs. Saxby and Farmer with reference to Electric Locking; but it is not my intention, and certainly no part of my duty as consulting engineer to the Amalgamated Society of Railway Servants, to discuss the claims of inventors. I have simply to consider and report upon the mechanical construction and practical working of various appliances and systems which have for their object the safe working of railways.

Nothing was said in my letter about signalmen being "unreliable or careless"; but it is a well-known fact, constantly proved by accidents and Board of Trade reports, that signalmen are liable to, and actually do, make mistakes sometimes, and that to prevent these mistakes resulting in collisions, a safe system of electric locking for signals is absolutely necessary.

The correspondence in your own columns and elsewhere shows that considerable doubt appears to exist as to whether the Spagnoletti system is or is not a safe one, and certainly the inventor's letter, page 452, does not contain any facts to enlighten your readers, nor to clear up this important question. **Clement E. Stretton.**

Consulting Engineer Amalgamated Society of Railway Servants.

40, Saxe Coburg-street, Leicester, Jan. 21.

[26777.]—MR. SPAGNOLETTI (26727) replies to Mr. Stretton (26710) as to his system of electric locking for signals; but we are no wiser than before. Mr. Spagnoletti takes up a great deal of space about "Mr. Stretton being a representative man and adviser to a society," &c.—as if all the railway world did not know that—but never says a word about how he gets over the defect complained of. If the man *does not* put the lever back, how can he lock it? I would refer him to the letter of "Rover," page 452, and ask him to explain. If Mr. Spagnoletti would illustrate and describe his system in the "E.M.," we could then all see for ourselves, and misapprehension would be removed. **J. Dixon.**

THE WIMSHURST MACHINE.

[26778.]—CRISPIN (letter 26736) is right in his suggestion—viz., that wire brushes would answer if substituted for the ordinary collecting combs; but in practice he will find there is difficulty in keeping all the points of the fine wires directed towards or touching the glasses; while if only one of the fine wires should get out of its proper place, it is so highly charged that great loss ensues.

I write after repeated trials, and therefore think he may accept the statement as one of fact.

A length of guttapercha-covered wire, with the end of the wire pointed and brought near to the plate, answers instead of a comb for plates up to about 12in. diameter, while for larger plates two such wires should be used as a substitute for each comb. All the multiple plate machines are so made up, and are so described in your earlier numbers; this cheapens their construction.

For the above-stated reason, and because there is no chafing on the plates, the pointed wires will be found better than brushes when used as substitutes for the ordinary collecting combs.

J. W.

[26779.]—IF "Crispin" (letter 26736, p. 454) will turn back to "E.M." of May 21, 1886, p. 258, as well as to "Original Experiments" No. 8, he will find that I have anticipated him upon the matter. I consider that one point, whether as a point or as a fine wire, is quite sufficient to take all the electricity accumulated upon any sector, and "that it is doubtful if any electricity is given off from the glass lying between each sector," which I think will probably be found upon experiment by building up discs, so that each piece of glass will be no larger than its tinfoil sector; to give at least as much electricity with so much the lighter discs, see No. for Dec. 31st, p. 390. I am also almost come to the conclusion that it is of no advantage to have points or brushes of jars or conductors in connection with both the discs simultaneously: I seem to get equally good results with "one" to each conductor.

January 21st. A., Liverpool.

MICROSCOPICAL—NUMERICAL APERTURE.

[26780.]—THE difficulty mentioned by "J. F. S." is a very natural one which has puzzled many. "J. F. S." says, "Theoretically they (an oil immersion and a water immersion of the same N.A.) should be alike."

Theoretically, a steamer with a screw of 20ft. pitch should advance 20ft. through the water at each revolution. So it would if there was no slip. Also, a dry lens of N.A. 1·0 should theoretically grasp spectra diffracted to as great an extent as those which are only capable of being taken up by an oil immersion of the same N.A. So undoubtedly it would if there was no slip. No one will doubt the superior brilliancy of an oil immersion of N.A. 1·0 to that of a dry lens of the same aperture. The *theoretical* illuminating power $(N.A.)^2$ is, however, the same for both. The amount lost through slip by the dry lens was evidently not taken account of in the *theoretical* formula. There is another element to be considered in addition to slip. Lenses of the same N.A. and power which have media of different refractive indices interposed between the front lens and object have front lenses of different curvatures—*e.g.*, a dry one-sixth of N.A. 1·0 would have a front lens of very deep curvature, while an oil immersion one-sixth of N.A. 1·0 would have one of a comparatively shallow curve.

The deeper the curvature of the front lens, the more difficult it becomes to make it aplanatic and achromatic. It is far more difficult to make a water immersion of N.A. 1·26 than an oil immersion of N.A. 1·27.

"J. F. S." is quite right: there is a great difference in favour of the oil immersion. This is accounted for by slip (loss of light by reflection, &c.) and unavoidable errors in construction.

Edward M. Nelson.

London, Jan. 20.

COAL ECONOMY—GOODS TRAINS AND PARTING COUPLINGS.

[26781.]—B. BAGSHAW (26730) says he does not believe in electricity for signalling; it has failed so often. How does he intend to work the block without? He says, "The plan that I have recommended will be the best to effect the object in view"—viz., safe working. What is the plan; where recommended? Will he kindly illustrate the automatic system he speaks of? Surely the Board of Trade and L. and N.W. Co. did not refuse to patronise so worthy an appliance? Perhaps Mr. Bagshaw will be a little more explicit as to how the ten per cent. is to be made on all railways. I am sure his fortune is made if he can show any board of directors how it can be done. Wages are to increase too! **Rover.**

"THOSE WHO LIVE IN GLASS HOUSES SHOULD NOT THROW STONES."

[26782.]—WHEN your valued correspondent, "A Fellow of the Royal Astronomical Society" (whose communications are, however, too frequently tinged with acid banter), takes upon himself, in letter 26685, to ridicule the "imperfect" knowledge of another, and to stigmatise likewise as "far from perfect" one of the most accurate driving-clocks in existence, he should at least be careful that the reasons assigned for his strictures are themselves correct.

"F. R. A. S.," in the letter alluded to, states that "the mere fact that the mass of star discs upon his negative are elongated in a north and south direction shows that apparently the driving-clock of his equatoreal is far from perfect." Exactly the reverse of this is the case: the elongation of discs in a north and south direction shows that the clock is acting perfectly, and that the irregularity in shape is caused by refraction, which must affect their shape with so long an exposure as 67min., especially upon stars having an altitude of only about 30°.

Perhaps you will permit me to remind your readers, as "F. R. A. S." has forgotten to do so, that the photograph in question, despite the slight defacement occasioned by the "lines" so unfortunately lauded by Sir R. S. Ball, is in itself a remarkable achievement: it is by far the finest taken hitherto of 42 M and the adjacent nebulæ, as it enlarges the limits of the nebulosity to an extent exceeding those of the celebrated photograph of Mr. Common by at least six or seven times.

Many of your readers, I know, would like that the many excellent letters of our friend "F. R. A. S." should contain fewer pungent personalities, which, while they raise a laugh on being read, leave afterwards a sympathetic feeling in our breasts, even sometimes for that greatest of delinquents, the South Kensington Institution.

Another Fellow of the Royal Astronomical Society.

TEMPERING AND DOCTORING STEEL.

[26783.]—HAVING experimented with a compound similar to that of Adam Schaefer (letter 26645, p. 392), I have come to the conclusion that the capabilities of the same are rather exaggerated. I tried wrought iron, Atlas steel, and cast tool steel. On wrought iron the compound had very little effect—only a slight hardening of the skin, and this only after several immersions. The Atlas steel became about as hard as saw temper after three immersions, one immersion producing hardness at the edges only. The fracture was like that of inferior spring steel. In breaking, it first bent and then broke suddenly. On cast tool steel it does not produce any appreciable effect, and can hardly be said to restore burnt cast steel. The mixture I used was composed of rosin 3 parts, charcoal 4 parts, linseed oil 3 parts, glycerine $1\frac{1}{2}$ parts. I tried other proportions, but they did not produce the desired result.

Some months ago I tried the muriatic acid and zinc bath on some small drills, but did not find it had any advantages over mercury.

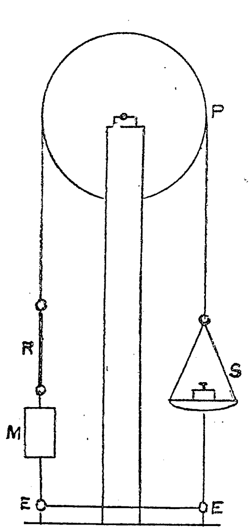
A. F. Shakespear.

Lüttichaustr 14, III., Dresden, Jan. 22.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60744.]—**Question in Dynamics.**—A very simple apparatus will serve to solve this problem experimentally. P is a wooden pulley, with a very



light axle running in two notches cut in bits of sheet brass let into saw-cuts in the tops of a pair of wooden uprights. A silk thread passes over the pulley, and to one end is attached the "monkey" M (mine weighed 7oz.) by means of an india-rubber band, the elasticity of which does duty for the muscular arms of the animal; S*a*, scale pan at the opposite end, is accurately weighted to balance the monkey. E E are the screw-eyes in the base of the apparatus, through which passes a thread attached to both M and S, and by means of it R is stretched 1in. On releasing the string, M rises about $\frac{5}{8}$in., S $\frac{3}{8}$in., the difference being due to the friction and inertia of the pulley. The case is really the same as that of two boats afloat connected by a cord; pulling the cord causes them to approach each other, and any other result is impossible by the 2nd law of motion.—W. A. S. B.

[61101.]—**Stars Visible from Bottom of Well.**—In answer to "Dubitans" permit me to quote the few following lines from Herschel's "Outlines," paragraph 61:—"We have ourselves heard it stated by a celebrated optician, that the earliest circumstance which drew his attention to astronomy was the regular appearance, at a certain hour, for several successive days, of a considerable star, through the shaft of a chimney." "Dubitans" will also find several references of a similar nature in Arago's "Popular Astronomy."—B. A., Handsworth.

[61111.]—**Hand-Saw.**—"T. P." inquires the difference in form and mode of using the hand-saw of a British or Oriental workman, and defines the latter as "having teeth leaning in the opposite direction." I would respectfully remind this correspondent—and it is a lesson which, for our good, requires to be more deeply impressed upon us as a nation—that what is not British is not necessarily Oriental. The British workman is acquainted only with the thrust saw, and not with the pull saw. Now the latter is a most useful and convenient tool to work with, and when only light timbers, not exceeding 3in. thick, have to be dealt with, is very superior to the saw used exclusively at home. It cuts clearly and evenly, less force is required, and you are never troubled with buckling or bending. The blades generally measure 35 centimètres long, seven centimètres broad, and one millimètre thick, and are fitted with an appropriate handle for pulling, the teeth being directed towards the hand, with very little side set. Such saws are made in France, and I have seen them in use there, in the provincial villages of Vaucluse, and along the Mediterranean coast. Here in Cyprus, where I am at present, they are used exclusively, and the saw of the British workman is almost unknown. I have examined a few while writing this, in search of a brand, with the result:—two are unstamped, other three are simply marked "Acier Fondi," while one has an addition, the name, "Peugeot Frères." All are distinctly of French, not Oriental, fabrication. Such tools are largely in use in Eastern countries, and, with other such things as locks with inverted keys, and screws with a left-handed twist, have earned for the Chinese and Japanese the unmerited title of being "upside-down people." In Alexandria I observed itinerant vendors of firewood (brushwood) cutting it up with great celerity into short lengths, suitable for local use. They employ a length of band-saw, placed diagonally in an upright frame, the sides of which form a gauge for the length, and the teeth of the saw being set against the operator, he quickly and easily gets through his work, by rubbing or pulling the wood against the fixed saw.—H. B. F.

[61131.] — **Electric Cautery.** — TO MESSRS. STEWART AND CONRY.—If Dr. Stewart will kindly send me a letter through the Editor of the ENGLISH MECHANIC, I shall be happy to lend him one of my 5s. ammeters, by means of which he can determine for himself the amount of current he requires, and report results. I shall be happy to lend E. Conry one of my instruments, provided he will kindly report on its adaptability for measuring small currents. The 5s. instruments will measure up to 5 ampères, and give trustworthy readings of $\frac{1}{10}$ of an ampère.—S. BOTTONE.

[61131.]—**Electric Cautery.**—My original query addressed to Mr. Conry, which has evoked so many replies, is, I think, most satisfactorily answered by Mr. Conry's last letters. "$\frac{1}{4}$in. platinum wire, No. 30 or 80, brought to a bright red, by three good Leclanchés" which are able also "to keep incandescent lamps going for twenty minutes" is certainly "the most economical and satisfactory" arrangement. Despite "Ohm's" sneers, I am greatly obliged to Mr. Conry for the formula in the Dec. 31 number, which I am perfectly able to use. Allow me to say to "Ohm" that, while I have already thanked him for previous letters, his abuse of me and my profession is quite gratuitous. My query was not addressed to him, and as I am a supporter of "Ours" for the sake of the information therein supplied, and put my query in civil form, there was no justification for his occupying the space he did. I seem to have excited his ire because I gave the resistance and did not at once comply with his request for the diameter of the wire or weight in grains. The reason which I gave, if nothing else, ought to have prevented the display of bad temper, viz., that I had not made the thing, and having had the resistance only given me, I quoted that. "Cautery" has now given him full details about it; but perhaps "Ohm" is one of those who, if a medical man wants a cautery, can supply him with a box at £15 to £20, and who insist on another box—at the same price, of course—being absolutely necessary for every other particular purpose. Is not the exhibition made by electricians in last week's issue, in their replies to 61400 specially, but also to 61399, sufficient to make him blush for *his* profession? A range from $1\frac{1}{4}$ to 4,000H.P. in reply to a simple arithmetical question shows well? May I submit to Mr. Conry that the second portion of my query—"How can the current flowing be accurately measured"—has not yet been fully cleared up?—A. DUNLOP STEWART.

[61131.]—**Electric Cautery.**—In reference to "Iota's" query *re* 5-volt lamp of 10c.p., my comment was general. I think you are quite right—it would take at least 6 ampères to work such a lamp. The incandescent lamps usually spoken of as 20c.p. are, I find, only 16 actual, and the best of them then require 60 watts in actual work. A bichromate battery of 3 cells should easily give 5 volts if all connections are well made; but the plates must be large, say 8in. by 4in., two in each cell with zincs same size between them, and for cautery work they could all be joined up parallel, if the plates are arranged to raise and lower; then if this is done by a spring with a treadle, this last can be worked by the foot, and the plates only partially submerged at first, so as to heat cautery as required, more of the plates being submerged as polarisation sets in. I note your remarks about Bottone's instrument. I have only to-day had a set put into my hands to test, and I shall do so and give results. I am very pleased to see reply from "Cautery." Pity Dr. Stewart did not put the query into this gentleman's hands at first! His No. 22 cautery wire is almost exactly same size as the Pt wire used in my experiment, and as it has been hammered out thin, it should have taken more current. "Cautery," says 12-15—this is rather wide; but as the wire has been filed down, that would reduce the sectional area, and so less current would heat it. I cannot allow "Cautery's" remarks about Sprague's galvanometers to pass without protest: they are neither complicated nor fidgety—whatever this last may mean. I have used his largest instrument with 5 circuits for years, and never worked with an instrument more to my mind. It was made by Mr. Sprague specially to suit work when a great amount of tests had to be got over quickly, and it was always a pleasure to work with; it had a range from ·0001 to 15 ampères, and with one Daniell would measure from 1 ohm to 5,000. Mr. Sprague brought out a galvanometer specially for medical men, which was really a fine instrument. Mr. Conry's remarks should be passed over. It was far from my wish to offend him; but as I have done so, I may just add that I would advise him to read carefully an extract from an essay which the Editor keeps continually before us. He says Dr. Stewart did not inquire about battery cells; yet query 61131 reads: "What is the most economical and most satisfactory arrangement for obtaining the heating of a cautery?" Perhaps the doctor could produce such a battery as Mr. Conry speaks of. Did Mr. Conry read the doctor's reply, p. 395, where he discloses such an array of bichromates as would almost make anyone weep for him? Was it in his reply or the original query that the doctor informed Mr. Conry that he was no novice in electrical science? I still say that the formulæ given, p. 395, could not possibly assist with this query: it would have been quite right had it been required to find the heat developed per second in a wire. The query, however, before us is the current required to maintain a platinum wire at a white heat—say about 1,500° C., and into this question neither specific heat nor weight enters further than the latter determines the diameter. Before Mr. Conry appeals to Mr. Sprague on this point, let him read the latter, 2nd edition, pages 300, &c. Now, *re* my remarks about Leclanchés, "Cautery's" reply shows how he and many others would read Mr. Conry's remarks on this battery—viz., that he recommended it for cautery purposes. I have seen incandescent lamps used off these, yet I am prepared to place any reasonable sum in the Editor's hands to be handed over to Mr. Conry if the latter will produce Leclanché cells which will maintain the current I named, 4·75 ampères, for one-fourth of the time he says he has used these lighting incandescents. I am aware that if the size of cells were increased infinitely, then even the Leclanché might do so; but I refer to the usual sizes to be met with everywhere. I name either Mr. Sprague or Mr. J. Brown to test the cells, and I am sure either of these gentlemen will readily give their time to test such cells. I must apologise for the length of this; but hope the importance of the subject may be my excuse, as it would be a pity that any of our correspondents should be wilfully misled. Having written to "Ours" now for 17 years, most of this time as "Ohm," I shall still continue to do so, Mr. C.'s remarks notwithstanding.—OHM.

[61132.]—**Glazing Pottery Ware (U.Q.)**—"Poor Potter" will find most of the information required on this subject in Spon's "Workshop Receipts," third series. It would take up too much space to reply to his questions.—W. HOLDER, Newport, Mon.

[61134.]—**Electro-Motor (U.Q.)**—This query was addressed to Mr. Bottone or Mr. Bowron; but it probably slipped their notice. Anyhow, in small electro-motors it is not the rule to make the resistance of the armature exactly equal to the resistance of the field-magnets. The winding partly depends on the form of the field-magnets and armature. In the case of Siemens H armature with vertical field-magnets, same as are advertised a lot, the resistance of field-magnets is often made twice that of armature; perhaps using No. 18 wire on armature and No. 16 on field-magnets.—W. HOLDER, Newport, Mon.

[61138.]—**Yacht Steering.**—I should be much obliged if "H. G." would kindly let me know the action of the patent steering gears he mentions. A wheel is just the thing I want to do without if possible, as it would take up a great deal of room on a 4-ton yacht.—G. H. V.

[61145.]—**Does it Boil?**—TO "WEALD."—I write far out of reach of back numbers; but, in any case, I have no wish to insist on any charge of evil intention where misunderstanding is easy and the occasion long past. "Weald's" expression, "natural air" is ambiguous; but certainly I meant that water gives off vapour more rapidly in vacuo than in air at any given temperature. I have just been reading the late Professor Clerk Maxwell's "Theory of Heat," and find his account of the matter particularly luminous, more so certainly than that of "A. E. F." Of course the point I am contending for is that water-gas is the same substance, whether formed above the boiling point or below, and that the amount given off depends on the temperature, and that the evaporative power of air is a question of temperature. A current of warm air will supply the necessary heat as well as any other source of heat. The amount of water-vapour in any space where liquid water is present is, if time be allowed for its diffusion, simply a question of temperature, and not at all of air, natural or artificial.—W. A. S. B.

[61145.]—**Does it Boil?**—So far as I can make out, "Weald" holds (1) that vaporisation is simply solution of aqueous vapour in air, and (2) that the steam produced in boiling differs from all other steam in that it merely "displaces" the air and is not dissolved in it. His first contention is easily disposed of by the fact that vaporisation (not merely ebullition) goes on more rapidly in a partial vacuum than in the open air (the quantity, however, being the same as when allowed to evaporate in a vessel of the same size containing air), whereas his theory would require the evaporation to be less, there being less air present to dissolve the

vapour. When evaporation takes place in the air the aqueous vapour is, in a certain sense, "dissolved" by it (in quantities varying with its temperature and pressure); but this is, so to speak, merely accidental, as the process goes on independently of the presence of air or other gas. If "Weald" has read "A. E. F.'s" admirable account of the scientific explanation of the process, he surely ought to have no further difficulty. I cannot see why "Weald" should hold the "displacement" theory of boiling, when it is so obvious that the vapour *diffuses* itself into the atmosphere just like an ordinary gas. All so-called "true" gases are in reality only vapours—e.g., hydrogen at N.T.P. is the vapour of the liquid hydrogen, which only assumes that form at enormous pressures and low temperature. The term vapour is applied to those gases which at ordinary temperature and pressure assume the liquid form.—REYMOND.

[61145.]—**Does it Boil?**—TO "A. E. F.," MANCHESTER, AND OTHERS.—What, now, is the evidence contributed against the view that vaporisation is a case of "solvent action" by atmo? "W. A. S. B." has objected, p. 438 (and "A. E. F." likewise) that water evaporates faster in rarefied air, whilst the sugar in the cup does *not* dissolve faster when the liquid (say tea) is withdrawn. But the comparison is unjust, because the sugar becomes enveloped in air, which nobody expects to dissolve it! Unfortunately, the density of liquid tea cannot be altered much, and nothing will persuade it to offer double accommodation between its particles as long as it remains liquid; therefore the analogy cannot here be put to the test. What matter if solvent air can perform one more trick than solvent tea can? "A. E. F.'s" explanation, p. 458, amounts to saying that where parboiling takes place, an occasional molecule here and there by a freak of nature has been effectually brought to the boil. This is not unlike the popular view that parboiling is a boiling beginning on the surface, but not yet pervading the whole mass of liquid. However, if "A. E. F." admits that "when a pool abates its level" solution is the case, will he not extend the admission to the cup of cold water which steams in the frosty air? ("Nun. Dor.," p. 353). And if the steaming cup of *cold* water is "solution," why not the steaming cup of *hot* water? And why not also the steaming cauldron on the fire, not yet boiling? Returning to "W. A. S. B.," surely "displacing" vapour is a sound idea, and not a "stumbling-block," p. 458? Boil water in a flask, and if vapour is generated fast enough, and the neck not too wide, the air will soon be be "displaced" from body of flask. Take also case of CO_2 liberated by acid at bottom of a test tube.—WEALD.

[61186.]—**Management of Launch Machinery.**—Is not this query rather too vague to meet with a response? for it seems to me that an answer would involve the writing of a treatise on the management of launch engines and boilers. Should not the querist procure one of the manuals? —though, as a matter of fact, he will find that nothing but practical experience will teach him. He will find much information in Reed's "Engineer's Handbook," published by Reed and Co., Sunderland, and a very useful little work entitled "The Safe Use of Steam," is published by Lockwood and Co.—J. T. M.

[61187.]—**Driving Feed Pump.**—It is not easy to answer such a question; for the advantages and disadvantages must depend on the construction of the engines and the surrounding conditions. As a general rule, it is advisable to keep everything off the shaft, except what must of necessity be put on.—C. K.

[61190.]—**Differential Feed.**—With a screw of four threads to the inch and left-handed, it is clear that to cut the same number of threads also left-handed the screw must be without movement while the bar turns: whereas if required to be right-handed, it must take twice the revolution that the bar does. In the former case, the end is obtained by putting a wrench on tail of screw, and in the latter by putting a wheel on bar twice the number of teeth of that on back shaft. For 3 threads, left-hand, while the bar makes 3 turns, the screw must make 4 − 3 = 1 turn in same direction as bar and wheels in the inverse proportion will do it, as 40 and 120, and if right-hand wanted bar makes 3 turns while screw makes 4 × 3 = turns, or wheels, say, 70 and 30. For ·148 pitch, or, say 3/20, or 20 threads in 3in. bar makes 20 turns while screw makes 12 turns less, or 8 turns, say wheels 80 and 200 for left hand, and (12 × 20) : 20 = 30 : 20, or, say, 130 and 80 for right-hand is very near. To save complication, if you add idle wheels so as to gear, you should add an even number of wheels.—T. C., Bristol.

[61191.]—**Wimshurst Machine.**—This query has been answered many times by anticipation. See back numbers.—VIDEO.

[61193.]—**Poisonous Alkaloids.**—There is no doubt that old flour is deteriorated, no matter how carefully it has been kept; but as to the existence of poisonous alkaloids, that remains to be proved. Fermentation of a kind goes on in the most carefully treated flour, and possibly some of the nitrogenous matters are altered; but what are "poisonous alkaloids"? Is not "poison" something that depends on quantity rather than quality?—BACAN.

[61202.]—**Fret Saws Breaking.**—The breaking of fret saws is somewhat of a mystery, for at times one will last for weeks, and at others a couple or more go without any apparent reason. I think that many are broken by the work getting an unconscious twist while the saw is actually moving through it at high speed. The saw should have as straight a motion as can be imparted to it: that is, straight as regards itself, for it is advantageous, I fancy, for the saws to describe a small arc as regards the line of cut. Some of our friends might turn their attention to this subject by answering the question, Which is the best movement for a fret saw?—SAML. RAY.

[61204.]—**Photographic.**—"Lens" should read up the subject of diaphragms in Capt. Abney's treatise, published by Longmans. The distance the stop or diaphragm should be placed in front of a lens is really a matter for trial.—I. H. J.

[61207.]—**Paper Doors.**—I have heard of a paper piano case, and see no difficulty in making paper doors or even paper houses. It is simply a matter of properly compressing the pulp which might otherwise be made into paper.—NUN. DOR.

[61208.]—**Watch.**—To polish parts of watches use rouge or jeweller's chalk with a brush, and, if necessary, clean off on bread. A bent balance wheel will have a tendency to wobble, and will therefore affect the time-keeping.—D. G.

[61214.]—**Pumping Set.**—A defect in one of the valves—most likely the bucket; but examine both. The bucket should draw practically air-tight, and if the inlet or suction is covered by water, no air ought to get in, even if the clack is defective. —NUN. DOR.

[61225.]—**Ironing Machines.** —There are several patented ironing machines; but none that could be considered "domestic." I believe some are in use by City manufacturers, and others were shown at the Inventions; but labour is cheap, and the gas iron answers all purposes—SAML. RAY.

[61226.]—**Barometer.** —This query is rather confused; but it refers presumably to a wheel barometer, and probably the weight and the tube require cleaning.—T. P.

[61230.]—**Watch Conversion.** — How can anyone tell "Watch Chain" what size lever escapement he will want when he gives only the size of the "top plate"? He might as well give the size of the pocket in which the watch is carried. D. G.

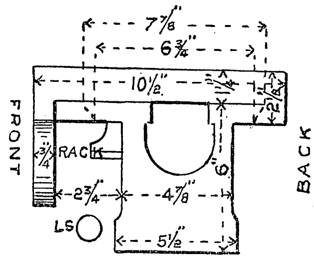
[61234.]—**Hardening Small Circular Saws.** —I find ordinary "pen" steel answers admirably. Float a piece of brown paper on water, make the saw hot carefully over an upright blowpipe, and lay it on the paper; it will be dead hard, and seldom warp. Temper as usual.—A. CLEGG.

[61274.]—**Portable Battery.**—The cells recommended by me are in daily use. Strange to say, they have none of the vices Mr. Conry enumerates; expect this must be due to some warm climate where he is—must be awfully hot. Glad he has given us the recipe for his private yet patented cell. Was this an Irishism?—OHM.

[61307.]—**Occultations.**—In connection with the query of "A. W." (p. 399), I would refer him to Mr. Woodside's graphic method of computing occultations, which he will find in the ENGLISH MECHANIC, Nos. 1075, 1076, 1080, 1083. I have used Shadwell's tables and Pearson's graphical method, but Woodside's is much easier, and quite as correct. I would point out to "A. W.," however, that to avail himself of this method he will require the "Elements" given in the *American Nautical Almanac.* It is to be regretted that the computation of occultations for places at a distance from Greenwich should be so laborious, as the observation of the phenomena is fascinating to amateurs.—J. R.

[61310.] — **Electricity.** — I am very much obliged for all the answers about an electric machine for killing dogs. I now find that the *Electric Review* of the 30th April, 1886, contains the description of such a machine, which was recommended to the Kimberley borough council by Mr. R. L. Cousens. I should much like to know whether this machine is still used, and without danger for the man who works it, and what it did cost to establish? Does Mr. Bottone not think that prussic acid may not kill instantaneously, and is nearly as dangerous for those who employ it as an electric machine? Morphia administered to one of my dogs, a young and vigorous bull-dog, produced a most wretched state of agony, and after sixteen hours of suffering, I was obliged to drown the poor creature.—W. VAN EYS, San Remo.

[61323.]—**Back Shaft for Sliding and Surfacing.**—To "J. H."—Thanking you for promised particulars, I send sectional dimensions. The



lathe is one of Selig's "Victorias," frequently advertised in the "E.M.," with 6ft. gap bed. The rack is in front; teeth ½in. pitch (nearly).—T. C. C.

[61332.]—**Speeding Millstones.**—TO "T. C., BRISTOL," OR "GLATTON."—Thanks for noticing my query. I am not wedded to the particular arrangement I named for driving; but am compelled by circumstances to adopt that method and no other. Would you still recommend 6 to 1 for the first motion? I was in hopes I should have had "Glatton's" opinion as well.—A COUNTRY MILLER

[61333.]—**Air Compression.**—The operation of compressing air is not one that can be carried very far with ease. It would perhaps have been well to explain whether it was only as an experiment, or to be on a scale that would serve some practical use. Some years ago, one of the underground Railway Co.'s, troubled with sulphurous fumes from the locomotive, made some experiments with a view to working engines with compressed air. It was found impossible to accomplish this compression at one operation, and the air was pumped from one vessel to another until the needful pressure was obtained; but the expense was found to be too great for profitable working. If the accounts of these experiments could be referred to, they might give the needful information.— H. C.

[61335.] — **Clark Soap Test.** — Wanklyn's standard soap solution is used in precisely the same manner as Clark's, with which, I presume, you are familiar, only that one cubic centimètre of Wanklyn's will precipitate one grain of carbonate of lime or its equivalent in degrees of hardness. One degree equals one grain of carbonate of lime. The estimation should be made with 70cc., not 100cc., as Clark's; washing soda will not precipitate carbonate of lime. Any further information with pleasure.—KCALBRED NAXELA.

[61366.] — **Super - Elevation of Railway Curves.**—The super-elevation of the outer rail on curves is usually determined by the following formula—

$$W \frac{V^2}{1{\cdot}25\ R} = x$$

Where W = gauge in feet,
V = velocity of train in miles per hour,
R = radius of curve in feet,
x = elevation of outer rail in inches.

Referring to the Portadown accident, the speed was 45 miles an hour, the radius of curves 30 chains or 1,980ft., and the gauge 5ft. 3in. Therefore—

$$\frac{5{\cdot}25 \times 2{,}025}{1{\cdot}25 \times 1{,}980} = 4{\cdot}2945$$

or about 4¼in. It must be specially remembered that the Irish gauge is 5ft. 3in.; and those who have not understood General Hutchinson's figures have doubtless only allowed for a 4ft. 8½in. gauge. —CLEMENT. E. STRETTON.

[61366.] — **Super-Elevation of Railway Curves.**—It is practically impossible to lay the super-elevation to suit the different speeds of trains. If a mean speed is taken, the faster passenger trains will wear the outer rail, and the slow or goods trains will wear the inner rail. The following formula from Molesworth's "Pocket-Book" may be useful to "Platelayer":—

Let E = elevation of outer rail in inches,
W = width of gauge in feet,
V = velocity in miles per hour,
R = radius of curve in feet.

We have $E = W \dfrac{V^2}{1{\cdot}25\ R}$.

Example: A train running 45 miles an hour on a curve of 30 chains, and gauge of 4ft. 8½in.; required the super-elevation of outer rail:—

45 × 45 = 2025
30 × 66ft. = 1980
4ft. 8½in. = 4·708

$$4{\cdot}708 \times \frac{2025}{1{\cdot}25 \times 1980} = 3{\cdot}85\text{in., or, say, } 3\tfrac{7}{8}\text{in. nearly.}$$

—JACOB GEORGE.

[61366.] — **Super-Elevation of Railway Curves.**—The formula for finding the proper elevation of the outer rail of railway curves is as follows:—

Let W = Width of gauge in feet.
V = Velocity in miles per hour.
R = Radius of curve in feet.

Then the super-elevation of the outer rail would be $W \cdot \frac{V^2}{1 \cdot 25\,R}$. In the case quoted, on G. N. of Ireland, it would work out thus—

Gauge (5ft. 3in.) = 5·25ft.
The square of velocity (45 miles) = 2025
Radius of curve (30 chains) = 1980ft.

Then $5 \cdot 25 \times \frac{2025}{1980 \times 1 \cdot 25} = 5 \cdot 25 \times \cdot 81 = 4\frac{1}{4}$in., as given by Board of Trade Inspector. Another practical rule which platelayers generally adopt is as follows:—

Let V = Maximum velocity of trains in feet per second.
G = Gauge of railway in feet.
C = Length of chord whose versed sine will equal the super-elevation.

Then $C = \frac{1}{2}\,V\,\sqrt{G}$. It works out thus for a speed of 45 miles.

Irish gauge (5ft. 3in.)
½ max. speed (66ft. per sec.) = 33
sq. root of gauge = 2·29 appx.
Then 33 × 2·29 = 75·57ft. length of chord.
English gauge (4ft. 8½in.)
½ max. speed (66ft. per sec.) = 33
sq. root of gauge = 2·17
Then 33 × 2·17 = 71·61ft. length of chord.

Stretch the tape on inside of outer rail, the distance from it at the centre to the rail will be the proper elevation in inches for a curve of any radius.—W. M. S.

[61391.]—**Soldering.**—I thank "Regel" for his plain and lucid remarks on the subject of soldering. At the conclusion of his remarks he asks "if any flux is required in coating iron with lead, except the usual preliminary dip in the hot grease bath?" The writer has seen sheet-iron coated with lead with a flux without being passed through grease; and iron also coated with zinc by being passed through a flux without grease. I don't know what the flux is. At the present time it would be very useful to me if any reader could inform me the flux used for this purpose. Would the killed acid mentioned by "Picklock" answer the purpose, if used on the top of the lead when molten, and the sheet-iron passed through it? If not, I should be pleased if he or any other reader could tell me the proper flux to use.—GALEN.

[61396.]—**Stains on Horse's Coat.**—"Under Strapper" does not say what colour his horse is; but I suppose it is a grey or roan. Does he not know that his horse if well strapped will have a beautiful new coat before summer, and at the latest by the end of May? Horses' coats do not grow much after the second or third week in December; the hair ceasing to grow becomes dead, and takes a stain almost as readily as a bit of cotton wool, and nothing, so far as I have been able to find out, will effectually take it out. With live hair it is quite different; use cold-water soap and a horsehair scrubber. The only preventive I know is to oil the quarter on which the horse lies down with neatsfoot or salad oil; but this must be done before the hair begins to stain, and done every night, washing off in the morning.—AN OLD MAN AND UPPER STRAPPER.

[61398.]—**Electric Battery.**—I should recommend a single-fluid cell of the size and plates you mention, and the following composition; but I should make the zincs the 3 and the carbons 2. I should also advise making the cells not less than 6in. by 4in. inside. The battery has no perceptible fumes, metallically, unless short-circuited, which would not happen with any ordinary care. I have found two of the great secrets of comfortable working with single-fluid lighting batteries to be (1) When you lift the plates out, place them all together in water, which if they are fixed to frames you can easily do, so as not to let the solution dry upon them. (2) If the light gets dim, stir the solution about by shifting the plates in it with a few small quick motions, or by stirring with a stick. Unless your 10c.p. lamps, however, are exceptional ones, you will want more than six cells to light them.—EDWARD CONRY.

[61399.]—**Leclanche Batteries.**—The bursting of the inner jars is usually fatal to a Leclanché. If adding sal-ammoniac will not make the batteries ring the bells properly, and they used to do so at one time, it shows the peroxide of manganese in the inner cell is exhausted, and you must either get fresh inner cells or open the old ones and add a small handful of "needle peroxide of manganese" to each, mixing it up well with the compound already there, and seal up again with pitch, leaving a couple of blowholes. This resealing is convenient but not absolutely necessary.—EDWARD CONRY.

[61399.]—**Leclanche Batteries.**—When the porous cell of a Leclanché is burst or cracked, it usually means that the cell will furnish a current so long as it will hold together. The secondary salts, which are formed in the working of the Leclanché battery, crystallise out inside the porous cell, in the space occupied by the loose carbon and oxide of manganese, and also within the pores of the cell itself. In the latter case, the crystals either fill up the pores, adding very considerably to the resistance of the cell, and finally closing the liquid conducting path for practical purposes; or it breaks the cell, thereby lowering the resistance by increasing the area of the conducting liquid. If "Colliery Manager" will communicate with me, I shall be pleased to give him any further information he requires upon the matter.—SYDNEY F. WALKER, 195, Severn-road, Cardiff.

[61400.] — **Electric Light.**—"Lancaster" is evidently entirely at sea in his reply to this query in last week's issue. "Ohm" also seems to be wrong. He wants to divide his result by 10. Evidently he has omitted the decimal point. The power available will be (as per my own reply in last week's issue) 2¾H.P. theoretical, and from 1½ to 2 actual.—J. H. H., Edenfield.

[61400.]—**Electric Light and Water Power.**—Very sorry that in setting down figures for calculation I added a cipher to the tons of water, making this 15,000. Please divide my results by ten. When this is done it reduces your power very much; perhaps, however, you could use 15 to 20 incandescent lights in the workings by day, and about the pit-head by night. If you could keep the dynamo continually at work, then it would well repay your outlay; but not so if you could only use the lights a few hours per day.—OHM.

[61400.]—**Electric Light.**—"J. H. H.", "Lancaster," S. Bottone, and "Ohm." all answer the same query. I pity the fog of the querist. Below I give a tabular statement of the various calculations of H.P. from the *same* fall of water:—

Horse-Power from same Fall of Water Calculated by Four Contributors:—

"J. H. H."	"Lancaster."	S. Bottone.	"Ohm."
Nearly 2¾ theoretical.	4,000 (four thousand).	2½ (about)	28

Is not H.P. always calculated per minute—i.e., so many foot-tons per minute = 1H.P.? Where have the four diverged?—R. S. T.

[61400.]—**Electric Light.**—"Colliery Manager" is, no doubt, somewhat perplexed at the slightly divergent answers given to his question by two contributors; he may take it, however, that the maximum power available will not exceed 1½H.P. If, however, a storage of water can be made, then, of course, a greater amount of power could be obtained for a shorter period. Is this feasible? Some time back I took in hand a matter of this kind, and after going over the ground I came to the conclusion that it would be best to form a pond, and obtain the required fall for the wheel by dropping it down a pit, the slope of the ground enabling the water to get away freely from under the wheel. If "Colliery Manager" sees fit to send me a rough sketch of the ground, and approximate section, I will do my best to put him in possession of the most economical method of dealing with the case, having regard to his requirements.—FRANCIS M. ROGERS, 21, Finsbury-pavement, E.C.

[61405.]—**Liquid Fuels.**—In estimating the thermal value of fuels, take the thermal value and multiply by amount present of each of the constituents contained in the fuel, and add the whole together, which will give you the thermal value of the fuel.

Thermal value per lb.:—
Carbon = 14,500 units.
Hydrogen = 50,000 „

Only the free hydrogen should be calculated, or the amount not combining with the oxygen in the fuel to form water. The hydrogen may be reduced to its equivalent of carbon by multiplying amount by $\frac{50,000}{14,500} = 3 \cdot 45$. Take an oil composed C = ·84, H = ·15, O = ·05; then ·144 = free H × 3·45 = ·497, and ·497 + ·84 = 1·337 = equivalent of fuel in carbon, and 1·337 × 14,500 = 19·387 units.—ELAG.

[61406.]—**Glow Lamp.** — Depends upon the voltage of the lamp, but I should say 7. The terminal attached to the zinc plate is the negative pole, and that attached to the carbon or copper plate, the positive. Connect thus: Join carbon of one cell to zinc of next with wire or other metal connection, and so on right through. You will thus at the finish have a carbon terminal at the end of your line, and a zinc at the beginning whatever be the number of cells.—EDWARD CONRY.

[61407.]—**Glass Spinning.**—A foot in diameter and a mile a minute mean 1,760 revolutions a minute. Does "M.R.C.S." mean such a speed as this? I suppose "M.R.C.S." means soda glass when he says "soft" glass.—R. S. T.

[61407.]—**Glass Spinning.**—1. The wheel should revolve with great speed, and the glass thread quickly thrown over it while at full speed. 2. The softest glass tube is the best for the job, carefully kept at fusing point. 3. The blowpipe-jet should be as near circular as possible, so as to give a long pointed flame.—C. A. W., Emberton, Bucks.

[61407.]—**Glass Spinning, Glass Working.**—In order to work glass with the blowpipe, it is necessary to procure the soft kind of glass, usually sold in long rods or pencils. The common kind of glass would only fly to pieces the moment the flame should be directed on it. If a person cannot procure those rods, he has only to go to one of the fancy shops and buy some glass toys—syringes, miniature bottles, &c.—as those are mostly of soft glass, and can be worked with the blowpipe into all conceivable shapes. From those toys I have myself made needle-caps for magnetic compasses, which answered their purpose extremely well. In spinning glass there are always two blowpipes and two burners employed, the flames being blown in opposite directions, so as to make both flames meet where the glass is to be held. I have no hesitation in saying that glass of the ornamental kind is the most resplendent thing in nature, and that glass thread is the most resplendent thing of its kind. Gems and precious stones, though somewhat of a more brilliant material than glass, are prevented by their smallness of size from offering any comparison with it in dazzling effects.—X.

[61409.] — **Coating Steel Springs.** — If "Tonge" requires his information for manufacturing purposes I fear the replies will not help him. I can give him the American method by which a boy can easily coat two tons of springs daily; but I regret I cannot make this information public. If "Tonge" will advertise his address, I will write him. The cost of coating with copper is nominal.—CANADIAN.

[61414.]—**Electromotor.**—TO MR. BOTTONE AND E. CONRY.—Size you mention would, I think, be almost too small to be useful for a sewing-machine. Should rather recommend you the one I described with drawings a few weeks ago. Yes, several. "Urquhart on Electromotors" is a simple and good book for a beginner, or Mr. Bottone's book if you want constructive details.—EDWARD CONRY.

[61416.]—**Early Railroad History.**—Some differences of opinion seem to exist with reference to the early history of railways, but so far as my researches have extended, it appears that "stone tracks," consisting of long narrow flagstones placed in parallel lines, were introduced about the year 1602; the "wooden way" seems to have been introduced at Newcastle, 1630. The wooden ways were first "plated" with iron to protect them at Whitebaven, 1738, and the first cast-iron plate rails were undoubtedly used at Coalbrookdale, 1767. Some authors unfortunately have considered the "stone tracks" and the "wooden ways" as the same system, and have confounded the "wooden plated ways" with the "cast-iron plate rails": hence the mistakes have crept in.—CLEMENT E. STRETTON, C.E., Leicester, Jan. 22.

[61418.]—**G.W. Engines, &c.**—The B. and E. engines having been reduced, the largest driving-wheel now on the G.W.R. is 8ft. Engine No. 10 is a new narrow-gauge express engine with 7ft. 8in. drivers. With the exception that the eccentrics are inside and all brazings outside, like the 7ft. class, it is the same as No. 9, of which a sketch and full dimensions have appeared in the "E.M."—SPECTATOR.

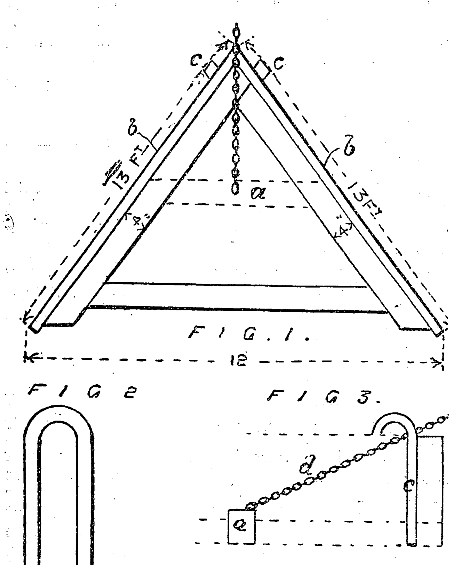
[61420.]—**Loco. Firegrates.**—The heating surface of loco. boilers should be about 80 square feet for each square foot of grate bars, and upon each foot of grate bars about 1cwt. of fuel should be burned per hour. About 240 cubic feet of air is the quantity required for the combustion of a pound of coal. From 8 to 11lb. of coal are consumed in evaporating one cubic foot of water.—AMATEUR.

[61424.]—**Model Steam Engine.**—Does "Angostura" mean that the cylinder is 1in. bore and 2in. long? If this is the case, perhaps I can help him. Why does he say cylinders? Vertical engines possess only on.—AMATEUR.

[61433.]—**Impurities in Gas.**—The tests for detecting impurities in coal-gas are very simple, and consequently merely show that the impurity is present. Quantitative tests require some manipulative skill. For sulphuretted hydrogen, moisten a piece of clean writing-paper with a solution of acetate of lead in distilled water and expose it to a jet of gas (unlighted) for not less than a minute; if the impurity is present the paper will turn brown or black according to degree of impurity. For ammonia, use turmeric paper in the same manner, damping it first in clean water, and if ammonia is present the paper will turn brown.

The paper can be bought ready for use, or made with spirits of wine and turmeric powder. For carbonic acid, pass the gas through clear lime water, and if the acid is present carbonate of lime will be precipitated. Lime water is easily made by shaking some slaked lime and distilled water together and then allowing it to stand for a few hours, when the clear water should be filtered through filtering paper. For sulphur compounds, to detect these, expensive apparatus is necessary, and some care is required in using it; this cannot, therefore, be classed with the above. Nearly all companies are required to see gas free from sulphuretted hydrogen under a penalty for failing to do so; but very few of the smaller ones are bound to free the gas from the other impurities. It is certainly to the interest of a company to take out the ammonia, as this is of value; but to remove the sulphur compounds requires expensive plant, and the smaller companies have therefore been left alone in this respect. The remedy is for the local authority to appoint a proper qualified person to test the gas at the works. Under the 1871 Act companies are to provide the necessary apparatus whenever required. If the local authority fails to appoint a gas examiner, two justices may do so, on the application of not less than five consumers. If the examiner proves to the satisfaction of two justices that on a certain day the gas was impure, the penalty is a fine not exceeding £20.—F. M. E.

[61434.—**Snow Plough.**—I send sketch of one that has been in use for some time and answers very well. First make a frame of 6in. by 4in., oak, as Fig. 1, setting the 6in. way of stuff upright, then bolt a piece across, 3ft. from the point



(as shown by the dotted line a) upon the top of the frame; two $1\frac{1}{2}$ elm boards should now be securely fastened outside the oak frame, as shown by b: these should be 12in. or 14in. deep. A piece of hoop iron should run all round the bottom, outside. A piece of $1\frac{1}{4}$in. by $\frac{1}{2}$in. bar iron must be bent as Fig. 2, and fastened across the point c to form an eye for the driving chain to go through, which must be fastened to the centre of a. Fig. 3 shows the chain d. Planks may be laid across inside and weighted with stones or bricks to keep it down, if necessary.—C. A. W., Emberton, Bucks.

[61435.]—**Storage Cell.**—TO MR. CONRY.—Depends entirely on the volts and ampères your lamp would require when fully lit. Impossible to give any information accurate enough to be useful without knowing these. The lightest form would be the E.P.S.; but as these are patented and strictly protected, you could not make or use them. Besides, it requires a considerable plant to make them successfully, and they are much more trouble when made than the Planté variety, which is free to anybody.—EDWARD CONRY.

[61438.] — **Measuring Cloth.**— The simplest way would be to weigh it, and calculate the length from the ascertained weight of a known length.—A. E. F., Manchester.

[61442.]—**Weight of Moist Air.**—In one sense "L. S. A." would be right in the way he understands the formula which he quotes; but this is not the way in which the author intended it to be understood. To make this plain in general terms, suppose S, S', and S'' to be the specific gravities of moist air, dry air, and saturated vapour respectively, as compared with a gas at the same temperature t, and the same pressure p; and let the corresponding volumes of the moist and dry air and the vapour be V, V', and V''. Then the weight of a cubic foot of the gas being taken as the unit of weight, since the weight of a given quantity of moist gas is equal to the sum of the weights of its constituents, we shall have—

$$V\,S = V'\,S' + V''\,S'' \quad \ldots\ldots\ (1)$$

But by Dalton's law, E being the tension of the vapour, the pressure of the dry air will be $p - E$; and by Boyle's law, since the temperature is the same for both, we shall have the volume of the dry air—

$$V' = \frac{p - E}{p} \,.\, V.$$

Next, considering that the volume of the vapour is to be estimated on the supposition that it is to be reduced to the volume of dry air, we have—

$$V'' = V'.$$

That is, V'' is also equal to—

$$\frac{p - E}{p} \,.\, V.$$

Substituting these values of V' and V'' in (1), we have—

$$V\,S = \frac{p - E}{p} \,.\, (V\,S' + V\,S'')$$

or—

$$S = \frac{p - E}{p} (S' + S'') \quad \ldots\ldots\ (2)$$

Hence, taking the weight of a cubic foot of dry air as the unit of weight, we should have the formula—

Weight of cub. ft. moist air $= \dfrac{p - E}{p}$ (weight cub. ft. dry air + weight cub. ft. sat. vapour). To show in what sense "L. S. A." would be right, take the same equation (1), i.e.—

$$V\,S = V'\,S' + V''\,S''.$$

Let now the specific gravity of the vapour S'' be estimated on the supposition that it belongs to a volume of vapour equal to the whole volume of the moist air, then—

$$V'' = V.$$

But, as before— $V' = \dfrac{p - E}{p} \,.\, V.$

And equation (1) becomes—

$$S\,V = \frac{p - E}{p} \,.\, V\,S' + V\,S''$$

or—

$$S = \frac{p - E}{p} \,.\, S' + S'' \quad \ldots\ldots\ldots\ldots\ (3)$$

Now, taking the weight of a cubic foot of moist air as the unit of weight, we have, in the way understood by "L. S. A."—

Weight cub. ft. moist air $= \left(\dfrac{p - E}{p}\right)$ weight cu. feet dry air + weight cub. ft. vapour.—MILVERTON.

[61444.]—**Dynamo.**—It is impossible for me to specify or localise the fault in your dynamo. That it is something trifling is shown by the sparking at the brushes, which proves that the dynamo works. I can only suggest the following causes. 1. The current leaks off either on the F.M. or armature. 2. The slits in the commutator are not in their proper position as regards the brushes: they should be under the brushes at the moment the flanges of the commutator are opposite the F.M.'s; there should be only two semicircles in the commutator. 3. The amount of wire is disproportionate. 4. Lamps of too high resistance are used in circuit, or too few are used. Why not send it to me?—S. BOTTONE.

[61445.] — **G.W.R. Compound.** — As "Compound" has applied to me I will tell him what I have heard of No. 7 and No. 8 from drivers and others on the G.W.R., although I have never seen either engine. They are four-cylindered compound coupled engines, with 7ft. driving-wheels, and were built last year, but are not in regular work yet. They have been trial trips, and have been back in the factory several times for alterations and improvements. No. 7 is narrow gauge, and No. 8 is broad gauge, but so built as to be capable of easy conversion into narrow. I am told that No. 7 is much cramped for room for cylinders, &c., between the wheels, and that in this respect No. 8 has a great advantage. In do not know on what section of the line between London and Penzance she will work. The following dimensions for No. 7 were given me by an engineman who had driven her:—Diameter of low-pressure cylinder, 23in.; ditto high-pressure, 14in.; pressure of steam in boiler, 180lb. to the inch; ditto low-pressure cylinder, 90lb.; total weight, loaded, 75 tons; 3,000 gallons of water in the boiler. Both pistons are connected to the same crank. He spoke well of her steaming and running powers; but another driver told me he preferred one of the 2,200 class with their new boilers.—T. PERKINS, Shaftesbury.

[61447.]—**Sugar in Boiler.**—I should advise "E. A. B." to discontinue the use of sugar as a scale preventive, and to soften the water by the lime process before putting it into boilers, cleaning out all acid at present in boiler first. There are more boiler accidents due to the use of scale preventive compounds, used in a rule of thumb manner, than what are generally supposed or acknowledged.—KCALBRED NAXELA.

[61449.] — **Dynamo.**—TO MR. BOTTONE.—I cannot speak very highly of wire-ring armatures. Nor do I think that a frame 18in. long, with field-magnets only 1in. in diameter, is at all proportionate. Still, if you can get about 2lb. of No. 18 wire on the armature, and about 10lb. No. 20 on the fields, you may get three or four 20's well lighted by it. Couple it up as a shunt machine, and let me know result.—S. BOTTONE.

[61450.]—**Engine Details.**—Connecting - rod $2\frac{1}{2}$ times the stroke, or, say, 23in. to centre, crank shaft should be $1\frac{1}{2}$in. diameter and crank pin $1\frac{1}{4}$in. diameter, and, say, 1in. to $1\frac{1}{4}$in. between shoulders for brasses. Fly-wheel usually 4 times stroke in diameter, that is, 3ft. and weight varies greatly, but 5 to 6cwt. may suit you.—T. C., Bristol.

[61450.] — **Engine Details.**—(1) Connecting rod, 9in. long; (2) width of crank-pin, $1\frac{5}{16}$in., diam. of ditto, $\frac{7}{8}$in.; (3) diam of fly-wheel, 36in. Weight. —This depends on what the engine is to do and what speed it is to run at for ordinary work with a speed of, say, 200 revs. per minute. I would make the rim weigh 85lb. or 90lb.—A. H. SHAKESPEAR, Lüttichaustr. 14 III., Dresden.

[61452.]—**Electrical Apparatus.**—If you will write to me (see Address column) I will send you diagram of switchboard. Only three batteries of the Upward kind were issued, as, according to a recent notice in one of the electrical papers, Mr. Upward and Messrs. Woodhouse and Rawson had hit upon an important improvement, and were reserving all further issue of the battery until such improvement had been perfected. I should say the best means of lighting your place would be by a cell, as follows: — Outer cell: Sulphuric and water, 1 to 15; inner cell, 8lb. bichromate of potash, 10lb. to 15lb. nitrate of soda, 20 pints sulphuric acid, and 50 pints of water. The above will make 10 gallons of solution, and costs about 5s. It is a good working battery, and on a large scale comes especially cheap, as it is possible to profitably recover more than one of the chemicals from the waste solution after use by electrolysis, precipitation, and crystallisation. E.M.F. slightly less than the Bunsen; about 1·7 and about 16 sq. in. of acting carbon surface required to produce one ampère, when zinc and carbon plates are not further apart than, say, $1\frac{1}{2}$in., this intervening space being occupied by outer and inner solutions of relative lineal thicknesses : : 1 : 2. The probable cost would depend on the lamps you used, and the number you had alight at one time, and the length of time for which you required them.—EDWARD CONRY.

[61454.]—**Hints on Purchasing Lantern.**—Of course, the important part of a lantern is the lenses; the condenser should measure 4in. or $4\frac{1}{2}$in. (the former to be preferred, if large enough) across. The front lens should be one which will give absolute flatness of field, straight lines, and perfect definition from the centre of the picture to its edge. The lantern body should be so as to allow a copious supply of air to the oil lamp (a paraffin one, of the three or four wick, or pamphengos description), and still be such as to keep all light inside when using the limelight. The limelight burner for so large a picture should be what is called a "mixing," or chamber, jet, requiring two gas bags under the same pressure to work it. My experience of lantern microscopes is limited, and I have usually made a lantern-slide of the object, and then thrown it upon the screen by limelight, thereby getting very much greater brilliancy than by any other method. As the lantern is for instructive, and not amusing, purposes, I should certainly not advise a biunial; there would also be a difficulty in fitting oil lamps thereto.—JAMES W. GARBUTT.

[61455.]—**Electric Bells.**—TO MR. CONRY.—I do not see how you can do it without using a relay, which is an arrangement difficult to describe on paper without a diagram, which I will send you if you will write, giving me your address. See Address column.—EDWARD CONRY.

[61456.]—**Caustic Soda Process.**—I saw some little time since in a foreign journal an account of the American torpedo boat *Peacemaker*. It stated that she was driven by means of the Honigman caustic-soda boiler, and further explained that this was an apparatus for generating heat through the agency of the above chemical, which had the property, if once thoroughly heated by a steam jet, of generating steam for itself for a considerable time after. If I remember rightly, the expression used was "generating steam for itself"; but I have an impression that it really so works by the evolving of a powerfully expansive gas, not actual steam.—EDWARD CONRY.

[61458.] — **Circular Saw Shaft.** — As an amateur, I suppose you would prefer making this; if so, have the collar forged on a piece of shaft

2ft. 6in. long. Your next best way is to buy the thing complete. Many tool shops no longer keep them in stock.—T. C., Bristol.

[61458.]—**Circular Saw.**—There would be one great advantage in turning the shaft for your saw in the lathe in which it is to be subsequently used in connection with, and that is, you can rely on it running true between your centres when it is finished, which you can't make sure of if you buy it ready turned. Eighteen inches will be a good limit for the length.—W. HOLDER, Newport, Mon.

[61459.]—**Galvanometer.**—As you have not stated what sort of galvanometer, you had better get hold of a copy of Sprague's "Electricity," which will tell you everything as to construction, winding, resistance, &c., and last, but most important, the why and the wherefore.—W. HOLDER, Newport, Mon.

[61459.]—**Coils for Galvanometer.**—I have an astatic galvanometer, with movable coils, as designed by Mr. Sprague. There are four coils—No. 1 size of wire ·035 = turns 340, R = 1·40w; No. 2 size ·022, turns = 610, R = 8·9w; No. 3 size ·010 = turns 3010, R = 180w; No. 4 size ·0039, turns = 6,000 R = 723w. Then make the instrument suitable for a large range of work.—OHM.

[61463.] — **Propulsion and Weight.** — The power required to propel a given weight differs in all three cases. In air, the amount of resistance depends on size, form, and speed of balloon. On water, the amount of resistance depends on form, speed, and displacement of vessel, and varies nearly as the square of the velocity. In the case of H.M.S. *Devastation* at 13¾ knots, it is ·14lb. per ton. On land, for trains, resistance varies directly as the weight; and where v = velocity, resistance in pounds per ton $= 6 + \cdot009\, v^2$. On tramways it is about 30lb. per ton; on ordinary roads, about 100 to 150lb. If an electric locomotive received its electricity from a conductor running parallel to the track, it might be considerably lighter than a steam locomotive of equal power.—ELAG.

[61464.]—**Iodine.**—Sea-weed thrown up by spring storms is collected, allowed to dry, and burnt in heaps, producing kelp. A certain amount of I is thus lost by volatilisation. The kelp is lixiviated, producing a solution containing alkaline carbonates, chlorides, sulphates, iodides, and bromides. Crystallisation removes the greater part of the first three, leaving I and Br in solution. Excess of H_2SO_4 is added, and liquor heated in iron boilers; the vapour is condensed in a series of aludels, which are of glass or earthenware, fitting end to end. MnO_2 is added little by little during the distillation. The I collects in the aludels. When all the I has come over, more MnO_2 is added, which sets free the Br. Another process is to acidify the liquor with H_2SO_4 and HNO_3 and agitate with petroleum spirit, which dissolves the I. This is shaken with NaHNO, which forms sodium iodide and iodate. From these salts the I is liberated by HCl. The I is purified by washing, drying, mixing with a little KI and sublimation. Any textbook of chemistry will give an illustration of the furnaces and aludels.—A. PERCY SMITH, F.I.C.

[61464.]—**Iodine.**—Sea-water contains an exceedingly small quantity of iodine; but certain plants, especially those growing in deep water, absorb and store up the element in their fronds. The weed is dried and burnt, leaving an ash called kelp, one ton of which yields about 10lb. of iodine. The kelp is lixiviated, and from the solution the carbonates, chlorides, and sulphates are crystallised out as far as possible, leaving a liquor containing chiefly bromides and iodides of the alkalies. There are several ways of obtaining iodine from this liquor. One method is to distil it with sulphuric acid and a little manganese dioxide; whereupon the iodine is liberated thus:

$$\underset{300}{2NaI} + \underset{294}{3H_2SO_4} + \underset{87}{MnO_2} = \underset{254}{I_2} + \underset{240}{2HNaSO_4} + \underset{151}{MnSO_4} + \underset{36}{2H_2O}$$

After obtaining the iodine, more MnO_2 is added, and the distillation continued, whereupon bromine comes over. Another method is to liberate the iodine by sulphuric acid containing nitric acid, and to dissolve out the halogen by petroleum. This solution is next treated with caustic soda, which converts the iodine into sodic iodide and iodate. On adding hydrochloric acid to the solution containing these salts, iodine precipitates thus:

$$\underset{750}{5NaI} + \underset{198}{NaIO_3} + \underset{219}{6HCl} = \underset{762}{I_6} + \underset{351}{6NaCl} + \underset{54}{3H_2O}$$

Iodine occurs in Chili saltpetre $NaNO_3$, and is extracted from the liquor left in refining this salt.—WM. JOHN GREY, F.C.S., Analytical Chemist, Newcastle-on-Tyne.

[61465.]—**Sinking Ropes.**— For sinking purposes flat ropes are best to use, because they are not so liable to spin in the shaft. The rule to calculate the strength of flat ropes is as follows:—W idth by thickness in inches, multiplied by 35 for charcoal iron, 55 for crucible steel, and 70 for plough steel, will give the working load in cwts. It is impossible to give size of drum and pulleys, unless the weight of material to be lifted and the probable depth of the shaft be known, whilst there are likewise other matters to be taken into consideration, in determining the kind of rope to use. If "J. O." will write me direct, I will give him what information I can.—J. WORLANDS, Mexborough, near Rotherham.

[61466.]—**Gold Gilding.**—If the surface on which it is put be reasonably smooth, it is sufficient to lay gold leaf on and rub it down smoothly on to the surface by means of a pad and burnisher. A soft, dry, flat camel-hair brush is the most convenient tool to take up the leaf with, first cutting the leaf to the size and shape required by a knife, on a sort of wooden artist's palette, held in the left hand. The brush will take up the pieces of gold leaf more readily if it be sharply rubbed on the coat, or head, or beard at each application—just two or three strokes—as this generates in the hairs of the brush a certain amount of statical electricity which oppositely electrifies the gold leaf, and, as unlike electricities attract one another, the leaf adheres to the brush.—EDWARD CONRY.

[61467.]—**Crayon Drawing.**—Conté crayons are about the best for this, with the little French tortillons for shading. First shade roughly with the point, afterwards blending with stump. I presume "F. H." refers to black and white, not pastel.—G. H. V.

[61468.]—**Brass Surface.**—The following is much used as a dead lustre for clocks; perhaps it may help you:—Water, 5 parts; nitre, 46 parts; salt, 3 parts; and potash alum, 46. Grind it all up together.—W. HOLDER, Newport, Mon.

[61471.]—**Steam - Heating.**—See "Box on Heat," published by Spon.—OHM.

[61471.] — **Steam-Heating.** — If "Ignorant" will give size and number of rooms and passages, temperature required, number of stories, and quantity of window in each room, and purpose each room is used for, I can assist him. If he advertises his name and address, I could assist him better, as the details would take up too much room in the "E.M."—A. GRAY.

[61471.]—**Steam-Heating.**—If you will bear in mind to take your steam to highest point first, and then lay your pipes with an incline to drain away condensed water, you will not have much trouble in laying the pipe to suit the rooms. You can return the condensed water to boiler from all rooms situated above the boiler. If any rooms are below boiler, you must fit a steam trap to end of pipes to economise steam. Boiler had better be fed with a float and usual lever arrangement, as you do not require a high pressure for heating purposes, say, 10lb. to 15lb.—T. C., Bristol.

[61471.]—**Steam-Heating.**—(1) The arrangement of the pipes must be governed by the architecture of the place and where the heat is required, and, therefore, should be settled after actual inspection of the place, and consideration of what is required. (2) If possible, the pipes are all arranged with a slight slope down to the boiler, so that any condensed water may drain back into it. Where this is not possible, drain-cocks are fitted on the pipes here and there, at the points where the condensed water is likely to accumulate, and before the steam is turned on full, these are opened and the pipes "blown out," like the cylinders of an engine before starting running in earnest, buckets, &c., being placed to catch the water. (3) By a donkey-pump or an injector, in the ordinary way. I do not know if there is any such work.—EDWARD CONRY.

[61472.]—**Damp Houses.**—Yes; saturate a circular piece of blotting or filter paper with a solution of cobalt chloride—dry it; this will be blue when dry, and pink when most. It was sold some years ago under the name of "Chameleon barometer"; it is not a barometer, but an hygrometer. When it was first introduced, I compared its action with wet and dry-bulb thermometers. When the thermometers showed saturation of air with moisture I called the tint of paper 0, when the thermometers were 13° apart in temperature the paper was blue, to which I assigned a value 10. I found I could detect a variation in the amount of moisture in the air as well by the change of colour of the paper as by the difference of readings of the thermometers. An account of my experiments may be found in the *Chemical News*, Vol. XXXI. pp. 88, 118.—A. PERCY SMITH.

[61472.]—**Damp Houses.**—I should think a scale might be made by the added weight by which dry plaster of Paris increases in any damp place. It is strongly absorbent of moisture from the atmosphere—increasing in weight and bulk, and turning mouldy. Strong sulphuric acid has also a considerable hygroscopic quality. A glass tube nearly filled with this will slowly fill itself if left exposed to the air. Perhaps something might be done with a graduated glass tube in this direction. Pure nitric acid also weakens rapidly if left exposed to the atmosphere. I believe its specific gravity becomes rapidly less according to the amount of moisture in the air, and, if I am right in this, a hydrometer floating in nitric acid would give evidence at once, as a scale could very easily be made of how much it should sink with each hour or 12 hours in a fairly dry house.—EDWARD CONRY.

[61473.]—**Cell.**—To E. CONRY. — I did not know you had published your address. However, I have given the recipe of the testing cell I referred to in the current number (Jan. 21st) under Replies to Queries (61274). The length of the cell, which I omitted to give, may be 6in. The top of the carbon should project well out of the mixture, so as not to have the brass clamp or leaden top nearer to the surface than about 1½in., in order to avoid "creeping," and if the leaden top be painted with Brunswick black, and also a ½in. of the carbon below it, it will increase the lasting power of the cell, and make it look all the better. One of these cells will ring a bell well, and they can be put up in houses as substitutes for Leclanchés, though for lasting power they are hardly as good in this respect as the glass-jar Leclanché; but they are immensely convenient and handy. If you want any further directions, I am advertising my address this week for one or two others who have written for it.—EDWARD CONRY.

[61474.]—**Silver Cell.**—Try the following: zinc, saturated solution of sal-ammoniac, chloride of silver, and a silver plate, not two or three small heavy portions of silver riveted together, the chloride being about ⅛ thick or more over the silver plate, and separated from the zinc by a thin strip of white flannel; also the zinc and silver plates should be within a ¼in. of each other. With the arrangement you describe, I do not suppose you would get much current out of the affair. The silver plate of Clarke's commercial cell exposes about 15 square inches of surface to the zinc. The soldering fluid you first tried is killed spirits of salts, i.e., hydrochloric acid that has already taken up all the zinc it will hold; it has lost the power of acting on zinc, so that of course you would not get any current.—EDWARD CONRY.

[61476.]—**Brass Foundry.**—If you consult the article referred to, you will see that each of your queries is answered. Fireclay for the bricks, hard coke for fuel, while the furnace itself is fully dimensioned.—J. H.

[61476.]—**Brass Foundry.**—Instead of mortar use fireclay made as soft as mortar, with silicate of soda—i.e., water glass. If you use firebrick, damp the firebrick well, and you will get a better joint. If you do not damp the firebrick, you can start your furnace the minute after it is up.—R. S. T.

[61477.]—**Name of Craft Wanted.**—It is a Chinese house-boat used on the large Chinese rivers by large numbers of the poorer classes who live altogether on the water, getting a living by plying with the boat as a bumboat or cargo boat, or in other capacity. Usually the wife stands at the helm, while the man works or goes on board or ashore, and the son and heir, if there be one, plays about the boat, with an empty air-tight gourd tied between his shoulders as a life-buoy, in case he goes overboard.—EDWARD CONRY.

[61478.]—**Lenses.** — If "B. B." refers to the front page of the issue in which his query appears, he will have little difficulty in finding out where to get the lenses he requires.—VIDEO.

[61479.]—**Medical.**—It is said that watercress has the effect of neutralising tobacco smoke.—F. M. ROGERS.

[61479—61480.]—**Medical.**—To remedy as far as possible foulness of breath, keep the stomach in good order by plenty of exercise, plain food, avoidance of late suppers and alcoholic drinks. To prevent the smell of smoke, do not smoke. To cover the smell of smoke or other foulness, make a weak solution of permanganate of potash, in clean water; one teaspoonful in two quarts will be ample. Rinse the mouth out well with this, but do not swallow it. I should strongly advise you to empty your physic bottles into the sink, unless they have been ordered you by a physician. Both quinine and iron are excellent tonics; but should not be used by those who do not want *toning*.—S. BOTTONE.

[61482.] — **To Loco. Correspondents.** — I extract the following from D. K. Clark's "Locomotive Engine," hoping it may be of some assistance:—"Obviously the firebox heating surface is by far more active for the evaporation of water than the surface of the flue tubes. Mr. Robert Stephenson, from experiment on a small boiler, having six sq. ft. of firebox surface and 40·5 sq. ft. of tube surface, found that while each square foot of the former evaporated 16lb. of water, the same

area of the latter evaporated only 3lb. Mr. Ed. Woods and Mr. J. Dewrance, on testing a modern loco. boiler, found that the first 6in. of tubes evaporated about the same amount of water as an equal area of firebox, the next 12in. of tubes about one-third as much, and the rest of the tubes but a small fraction, the first 6in. of tubes doing more work than the next 60in."—L.B. AND S.C.R.

[61483.]—**Heating Water.**—You describe an impossible experiment, and therefore correct answers cannot be given. Under the conditions given, the water would have no chance of extracting all the heat from the pipe, for the latter would be blown to bits the instant that an attempt was made to fill it with water.—EDWARD CONRY.

[61483.]—**Heat of Water.**—In an open pipe the water could not be raised more than to 212°, a portion of the water being converted to steam until the pipe is reduced to that temperature. Supposing that the pipe weighs 22lb. (neglecting the bottom) the sensible heat lost would be $1050 - 212 = 838°$, that is $838 \times 22 = 18{,}436$ in all. Let x = pounds of water evaporated, then we have the equation $9x\ (966 + 180) + 9\ (6 - x)\ 180 = 18{,}436$, from which x will be found = 1·025lb., leaving 4·975lb. of water at 212° in pipe. The latent heat of steam being 966°—T. C., Bristol.

[61489.]—**Speeding Engine.**—If there are balance levers to the governor, you can simply shift the weights farther out or add heavier weights. Either way will cause the governors to rise at a lower speed; or you may put in fresh gear in the proportion of $\frac{32}{7}$, your present gear being $\frac{32}{8}$. You do not state whether governor works a throttle or a cut-off valve on back of main slide.—T. C., Bristol.

[61490.]—**Acoustic Telephone Construction.**—If you will write me, I will send you a sketch as you ask. My address you will find in the proper column of the number in which this appears. These telephones are much more simple than the others, and will work over long distances. I have put them up so as to work well over more than a quarter of a mile, and have heard that they can be used up to a mile. The same instrument acts as both transmitter and receiver, as in the old Edison telephone.—EDWARD CONRY.

[61491.]—**Copper Castings.**—Copper is not reliable for castings, being spongy below the surface. Occasionally when copper castings have been wanted, as for friction clutch linings and caulking rings, we have got over the difficulty by casting plenty of head, and turning off. The addition of a little zinc will make it cast better; but with copper alone it is impossible to get soundness.—J. H.

[61492.]—**Cells Required for Motor.**—One pint bichromate cell will work your motor; six such cells will cause it to drive a sewing machine.—S. BOTTONE.

[61492.]—**Cells for Motor.**—If your cells are in good condition 3 in series should work it; if not, you will probably require 6 cells connected, 3 in series and 2 in parallel to increase the current.—W. HOLDER, Newport, Mon.

[61493.]—**To Change the Colour of Diamonds.**—Expose them to a good high heat (nearly white hot) in a current of oxygen gas. They will then burn to carbonic acid gas. That will effectually change their colour and value. That is the *only* practical way.—S. BOTTONE.

[61494.]—**Spur-Wheel Query.**—The proper method is the cycloidal, the curves being obtained by means of rolling templet circles. This has been described several times in back numbers. See No. 941, p. 99; No. 943, p. 143; No. 992, p. 84; No. 1,103, p. 242; and others beside. If you have not these numbers, and cannot obtain them, I will reply at length.—J. H.

[61495.]—**Cooling Composition for Hot Neck.**—The following is a valuable formula:—Melt 16lb. of tallow (don't let it boil), and dissolve 2½lb. of lead acetate (white sugar of lead); then add 3lb. of black antimony, and agitate the whole mass until cold.—W. HOLDER, Newport, Mon.

[61499.]—**Storage.**—Power for power, the electric locomotive carrying storage batteries is heavier than the steam-engine locomotive. The utility of the former is for situations where either the steam-engine cannot be employed or its use is undesirable, as for places where there is natural water power but no coals, or for crowded cities, &c., and where there is natural water power, even if coals be present also, the electric locomotive is far cheaper. It is possible that, owing to the better possibility of perfectly softening and annealing a small copper wire than a large one, stranded conductors, composed of several small wires, are for the same bulk of metal of slightly better conductivity than solid conductors; but in the usual employments of copper conductors the only difference recognised is that the stranded conductor, being more flexible, is handier.—EDWARD CONRY.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last, W. Holder has replied to 61132, 61134.

60926. Hokey-Pokey and Coker-nut Candy, p. 269.

61221. Cutters, 356.
61229. To Mr. Striffler, 356.

QUERIES.

[61503.]—**Radial Axles.**—Will anyone who knows the G.N.R. say if the new 7ft. 6in. exp. engines have a leading radial-axle box? I see it is stated in the "E. M." that the new G.W. engines, with 9in. less wheel-base, have difficulty in turning sharp curves. If this is so, is not there more difficulty with the G.N. engines, as they have 19ft. 1in. wheel base?—SPECTATOR.

[61504.]—**Double Electric Bells.**—TO MR. R. T. LEWIS.—In Vol. XL. p. 526 of the "E. M.," you gave a sketch of these double-gonged bells. Looking through "The Telephone, &c.," by Prescott, he says on page 383: "In double bells of this kind the line circuit is never broken by the vibrating armature, the effect of this movement being merely to shift the current from one coil to the other. This, in some particular cases, is an advantage of considerable importance." Does Prescott mean by this that three or four of these bells could be connected in series without interfering with each other? It seems to me, by having the armature arranged with a double contact, same as used in the above, two ordinary trembling bells might be made to work satisfactorily in series; so should be glad if you would give a sketch of the connections, supposing it is possible. Please understand I do not doubt two ordinary bells will work together from one push. Thanks to your instructions in back volumes, I have two working in multiple arc at the present moment for telegraphic purposes, though I am told they (the call bells) must be in series, so should be very much obliged for your opinion. By the way, there is a capital short-circuit bell described in this week's (Jan. 14) *Telegraphic Journal*, with an illustration.—M.M.I.SC.S.

[61505.]—**Eyepieces for 3⅛in. Telescope.**—I want three astro. eyepieces for above telescope, and should be glad to know what powers would be most useful. The telescope is 70in. long. Is it any the worse because the focus is so long?—ENQUIRY.

[61506.]—**Compound Engine.**—A compound engine, 18in. stroke, 150 revolutions per minute; boiler pressure, 90lb. per sq. in.; maximum horse-power required, 350. The steam is exhausted into a condenser, the vacuum in which is to be maintained by an independent engine. Will any of your readers inform me what is the readiest method of determining the diameters of the cylinders?—B. PAYNE.

[61507.]—**Condensing Benzoline.**—Chemical friends please reply. In cold weather benzoline condenses in open air at tap to semi-solid. Can it be compressed in this state for use in any place where liquid cannot be had?—T. WOOD.

[61508.]—**German Root Words.**—Will anyone who knows kindly say how a list of roots of the German language might be formed by the aid of a dictionary alone? What are their characteristics, and may each of the irregular verbs be taken to embody a genuine root form?—J. SHIPPAM.

[61509.]—**Syrup for Cordials.**—Will some maker of cordials, as sold by mineral-water makers, tell me how the syrup is made so thick and clear—in fact, as clear as water? I use glucose, as I believe they all do, but I cannot get my syrups bright. Is the glucose boiled, and with what proportion of sugar? Any hints will oblige—COUNTRY MAKER.

[61510.]—**Roller Covering.**—Will someone kindly say if there is a cement for fastening cloth on iron rollers under leather? Is so, what it consists of and how used? We are using white-lead, but it does not answer for our work; and what is the best cement for piecing leather?—W. A. W.

[61511.]—**Dynamo.**—I have a 100c.p. Gramme, its reputed efficiency being 45 volts and 6 ampères at a speed of 1,500 revolutions. The diam. of pulley is 3½in. Will some of our electrical friends kindly inform me the following particulars? (1) How many lamps and voltage this should light? (2) What power gas-engine I require? (3) Will it be necessary to attach a flywheel to dynamo to insure steadiness? (4) What lamps are recommended as giving the best results? (5) What gas-engine is recommended for small cost and economy? My address will be found in your advertisement column for answers to last two queries.—ANXIOUS IMPROVER.

[61512.]—**Magic Lantern.**—Will someone be kind enough to tell me how to fix a kaleidoscope to the lantern, so that when revolved it will show the changes of the screen? My condensers are 3½in. Is it necessary to have the circular glass (holding the coloured glass) of the same size?—J. H.

[61513.]—**Incandescent Lighting.**—TO MR. BOTTONE.—I am now fitting up castings to your directions given Jan. 29, 1886, No. 58666; but with careful winding can only get 2½lb. wire on armature. Please say whether I am to alter quantity of wire on fields. Also, what power lamps will be the best to use, and number of same dynamo will light?—DYNAMO.

[61514.]—**Lining for Accumulators.**—Will any reader of the "E. M." kindly inform me the best substance for lining wood boxes to use as Planté cells, other than lead—any kind of varnish or inexpensive non-conductors not readily acted on by the sc. acid?—VOLT.

[61515.]—**Photographs.**—TO R. A. R. BENNETT, OR OTHERS.—I would be obliged if you could tell me if anything can be done with a very much over-developed negative. It has been developed into a positive.—DUSTY MILLION.

[61516.]—**Gramme Dynamo.**—I have made a Gramme carcase, same as described by Mr. Eaves some time ago (30-lighter), only with one pair of fields. Armature 6in. long, 4⅞in. diam., 16 cogs (sheet-iron rings); channel of pole-pieces, bored 5in. diam.; yokes, 18in. long, 6in. wide, 1in. thick; F.M.'s 3in. diam., 7in. long, best wrought iron, plenty of room to wind F.M. 1½in. deep with wire, making fields when wound 6in. diam. What size and quantity of wire shall I put on A. and F.M.'s? How many 20c.p. Swan lamps should I get? What speed ought it to be run, and what H.P. engine will it require, and what should be the output, volts, amps.? Is there any danger of A. heating with long run? Each ring has about 1-32in. insulation from the next, with air space between each stud which hold ring to spider. Pole-pieces and yokes are cast in one piece.—YOUNG GHAZI.

[61517.]—**Mechanical Piano Playing.**—Can anyone tell me how to construct an apparatus for playing the piano by the use of perforated paper. I have seen an advertisement of an instrument styled the "pianista," which has apparently bellows like a harmonium, a crank is turned, and perforated paper employed. Is there any simple apparatus that can be afixed to the keyboard, and removed when not required?—SM.

[61518.]—**Gas-Engine.**—In a book on this motor, it is said that a hot cylinder lowers the practical efficiency. In another part it states that they are generally worked with cylinders at 100° C. I think these two statements are conflicting. Will some reader kindly explain them?—A. R.

[61519.]—**Lead Cylinder.**—What would be the bursting pressure of a lead cylinder ½in. thick of the following dimensions: Length 2ft., diam. 18in.?—L. W. D.

[61520.]—**Brass.**—I bought a thermometer not long ago, and after a few days, on cleaning it, the brass fittings literally dropped to pieces. On inquiry as to the cause thereof, the optician informed me that brass alway does so when exposed to sudden changes in the atmosphere. The thermometer had only been used for registering the cold on frosty nights. I have noticed the same results with brass that has been much in sea water. What is the nature and the action, and are all alloys similar to brass, such as gun-metal, bell-metal, &c., subject to it? If the zinc in brass is the metal acted on, would a small amount of it in gun-metal cause it to spoil when exposed, and, if not, what would be the largest proportion allowable?—G. M. S.

[61521.]—**Does Iron Fossilise.**—In wandering some time ago in a mountainous district, I happened to pick up a piece of brown stone having imbedded in it a foreign substance, which, to all appearance, was an iron or steel screw, which had become fossilised, the threads of the screw being distinctly visible; I would wish, therefore, to be informed whether iron ever becomes fossilised?—IVONAR.

[61522.]—**Questions as to Evolution.**—Can any of our biological readers inform me if there is any proof that the "pineal gland" of the human brain, which has so long been a riddle to anatomists, may be the remains of an ocular structure, and whether there is in some other animal a more fully developed pineal gland? Also the webbed feet of the Ceylon diving boys: is it known if they are remnants of once more perfect webbed feet, or are they recently appearing?—GERARD SMITH, M.R.C.S.

[61523.]—**Bell Circuit.**—Can earth be used efficiently as a return bell circuit? If so, what is the best way of making earth?—ROSICRUCIAN.

[61524.]—**Universal Cutter Frame.**—TO "J. H."—I have just completed a lathe (described by you in Vol. XXXVIII. "E. M."—a cheap lathe), and am going to put overhead motion to it. Will you kindly give me dimensions of a pattern for cast iron (not malleable) of a cutter frame for grooving taps, &c., suitable for the slide-rest on page 444 of above vol.? Also size of cutter spindle and pulley on same?—W. H. W.

[61525.]—**Racing Canoe.**—I wish to build a small racing canoe (sailing), with fixed false keel instead of centreboard; but wish to be able, with reduced sail area, to use her for cruising; length not to exceed 11ft. over all. Will any of our kind correspondents please give beam and depth suitable for this length, distance of greatest beam from stempost, with, if possible, on a small scale, midship section, distance of steps of masts from bow, height of masts, and length of main and mizen booms and gaffs. Sail plan on the Yankee principle (lugs). Please don't be afraid of putting too much canvas on, as I find that by adopting the Yankee fashion of sitting on deck to windward the craft will stand a lot more canvas than I have seen on any of our Thames canoes.—SHAMROCK.

[61526.]—**Wheel Barometer.**—Will a generous fellow-reader kindly give me a little assistance? My barometer records too high, by 5-10in. How can I rectify? I should also like to know how to re-connect the under pointer with its key spindle. I mean the small hand intended to mark last reading. I could until lately do this by using a key like a large watch key on a spindle below the dial; but now the key turns without moving the hand, the connection, whatever it was (cord or wheels), is severed or out of gear, and I cannot find the way to ascertain what is wrong. I presume the dial must be taken off. To effect this, the large hand must first be removed. This I cannot do. It is quite fast on its spindle; seems riveted. I should add that the door at the back does not give access to the movement I speak of. Please help me.—T. G., Birmingham.

[61527.]—**The Agar-Agar Cell.**—Has the agar-

agar silver chloride cell been described? If not, will someone kindly do so?—A. DUNLOP STEWART.

[61528.]—**Seeds for Microscopic Objects.**—Will some of your readers kindly give me the names of the seeds which are most interesting as microscopic objects, either from beauty of markings or other peculiarities?—LAVANT.

[61529.] — **Mathematical.** — Will some reader kindly give me the formula for obtaining the size of a drum or bobbin to hold a given length of rope of a given diameter, the diameter and length of the barrel of the drum alone being given? Also, when the diams. of the end of the drum and of the barrel are given to find the length it will have to be to hold the given quantity of rope? In both cases, inside measurement is wanted, of course.—E. M.

[61530.]—**Ferrous Oxalate.** — Will Mr. Bottone kindly let me know if ferrous oxalate developer is as efficient for inst. exposure on Eastman's paper as the Eastman's developer?—G. H. V.

[61531.]—**Lantern Transparencies.**—Will someone kindly give me full particulars for taking ¼ transparencies from ½ negatives. I get excellent results by contact printing, but, of course, only get part of the picture. I want to get the whole of a picture contained in a ½ or 1-1 neg. on to a ¼ transparency, but cannot see how it is done.—A. P.

[61532.]—**Varnish for Transparencies.** — In using water-colours, I find it is impossible to spread them on the photo. without coating them with some substance. I have used ordinary negative varnish, but should be glad if someone could recommend something better, if there is nothing made expressly for the purpose.—A. P.

[61533.]—**Speed Wheels.**—Would J. H. Evans, or some other engineering friend, write a book upon speeds of wheels all ready worked out, as I may call it a ready-reckoner, as many of my country friends often ask me if such a book is published? I am sure such a book of the kind would meet with a ready demand.—A COUNTRY MILLWRIGHT.

[61534.]—**Lathe Tools.**—A short time ago I made some lathe tools from square steel, ⅜. When I tried to harden them in water, several cracked. What is the cause of this, and remedy? It is very annoying after spending so much time in shaping them.—TOOL STEEL.

[61535.]—**Fret Saw.**—I have made a fret saw, which bolts down on lathe bed. It has two arms, like the Roger machine, with a wing nut at the back to lighten the saw. During the down stroke, the saw becomes very loose. Have tried to remedy the fault without success Can anyone suggest a remedy?—W. M.

[61536.]—**Organ Blower.**—I propose to blow an American organ (two manuals and pedals) with a small steam motor, working at a pressure of about 40lb. to the sq. in. I should like the opinion of "T. C., Bristol," and others, as to the practicability of the scheme. I intend to raise the steam by gas.—FLOREO.

[61537.]—**Bleaching Silver.** — Will any reader kindly inform me what the solution is composed of for bleaching silver jewellery, and the process of using it?—IMPROVER.

[61538.]—**Straightening Wire.**—Will any of your kind readers practically tell me how to straighten round wire, iron, or brass, from the coil without marking it, say from No. 3 to No. 16 wire gauge? I, having a lot to straighten and to cut into different lengths, should like to know the best possible way to do so.—P. J. W.

[61539.]—**G.W., L. and S.W., and L. and N.W. Locomotives.**—Can anyone give me the dimensions of (1) G.W. 806, 2201, 2211 classes, and the numbers of all the engines in these classes; (2) L. and S.W. 135, 348, 445 classes; (3) L. and N.W. 1678 Airey, and the numbers of similar engines?—V. J. B.

[61540.]—**Portable Engine.**—TO MR. BOTTONE.—I have made a model as above, 15in. long, 9in. high, boiler and firebox of wood, motion work of metal, no cylinder. I wish to drive it by electricity from firebox. Please advise me as to construction, and arrangement of motive power, and battery power required.—ELECTRICITY.

[61541.]—**Polish.**—In No. 1,125 "E. M." is a recipe for brush polish. I made some according to recipe: two parts French polish, and three brown hard varnish. When applied to the work, it was as tacky three weeks after as when laid on. I used brown hard oil varnish. Should it have been spirit varnish?—W. M.

[61542.]—**Clock and Sundial.**—Lockyer's "Astronomy" (Macmillan, 1886), page 197, par. 416, reads: "When the earth is in perihelion, the real sun moves fastest, and therefore will gain on the mean sun, and the dial will be before the clock. When the sun is in apogee, the mean sun will move fastest, and the clock will be before the dial." Is this correct? I always thought the facts were the reverse of this. Will someone kindly explain?—W. GODDEN.

[61543.]—**G.W.R. Locos.**—Can anyone say where No. 378 ("Sir Daniel") G.W.R. was built—runs from Liverpool to London?—C. BAYLEY, Oswestry.

[61544.]—**Darning Machine.**—I have lately got hold of a darning machine, but I cannot make it act. I see by my back volumes of the MECHANIC that an advertisement appeared of it in 1876, and it seems complete by the illustration accompanying the advertisement. It has fourteen needles, which are moved forward by a rack and pinion, which forces them through the work that is held by a clamp moved by a lever from above. Will any of our readers say whether it was a success or not, and how it was intended to act?—F. C. A.

[61545.]—**Railway Coupling.**—What pull is the ordinary screw coupling calculated to exert?—S. O. C. C.

[61546.]—**Harmonium.**—I have a harmonium with one set of reeds. I contemplate adding one half set more (treble), same pitch. Would it be an improvement, and would the bellows be large enough?—JOHN BEGG.

[61547.]—**G. and S.W. Locos.**—I have read with interest in your valuable paper various descriptions and opinions of the locos. of the M., Caledonian, and other railways, but never of the Glasgow and S. Western. Would Mr. Stretton, or others of our correspondents, kindly furnish me with their opinion of our bogie engines?—G. AND S.W. FITTER.

[61548.]—**Shipbuilding.**—Will one of your numerous readers who are experienced in marine engineering and shipbuilding (modern practice) give specific information on the following (accompanied by sketch, if necessary)—viz., method of boring out stern tube and getting the ship ready for launching?—NOVICE.

[61549.]—**Coil.**—Is it a settled fact that cotton-covered fine wire will not do for the seconary of spark coils? Is there any way of treating cotton-covered that will make it equal to silk-covered for spark coils? If not, why is such a wire as No. 40 covered with cotton, and what is it used for? Also, Can I make the ebonite tube for a spark coil by bending a piece of sheet iron round a cylinder and joining it with cement?—COIL MAKER.

[61550.]—**Interest.**—From $P = A\frac{R^n - 1}{R^n}$; when I know P, the principal or loan, A the constant annual payment, and n the number of years in which the loan is redeemed, how can I determine r, the rate of interest which is being charged, by a direct math. process, instead of by guessing and trying? For example, if a society lends me £100 on condition of my paying annually £7 for 40 years as repayment, how can I directly ascertain at what rate I am paying interest on the outstanding balance under such an arrangement? R is for $(1 + r)$; r is one year's int. on £1. Compound interest.—WEALD.

[61551.]—**Flow of Water through Pipes.**—Will any one of your correspondents kindly give me some information on this subject? For instance, I have a 24in. pipe sewer at an inclination of 1 in 100. From the outlet of this pipe I can get an inclination of 1 in 20. What size of pipe should I employ to take the water now coming through the 24in. pipe, of which the length is not known or assumed to be 100 yards? The question is this: Given length, diameter, and inclination (or diam. and inclination only) of pipe, what size of pipe must be used to take the same water at a greater or less inclination?—ST. GEORGE.

[61552.]—**Flat Foot.**—I have lately rather suddenly become lame in my left foot. I have told been it is a flat foot, and incurable. It got so bad from my persistence in walking that it was painful to put to the ground. Rest brings it round; but when I walk for a little time I begin to feel it again. I should like to know if it is really considered incurable, and if there is any means by which a walk of ten miles a day can be gone through, or must I give up employment? What are the causes?—J. C.

[61553.]—**Etching Ground.**—What is the composition of a transparent dark etching ground, such as Rhind's, sold by Winsor and Newton? All the grounds that I have hitherto seen recommended for etching contain wax, which, by assuming a rough surface after being melted upon the plate or deposited from a solution in chloroform, renders the ground somewhat opaque or semi-transparent. Moreover, a ground containing wax is not deposited well and evenly upon the plate from a chloroform solution. I have tried paraffin wax, and also the purest wax, which are very different in their composition. Now Rhind's ground is all that could be desired. It is deposited quite evenly from a solution, and the plate is perfectly visible through it, and is as soft as wax to the needle.—W. HOLDEN.

[61554.]—**To Mr. Bottone.**—Would the above gentleman please answer the following query? I have made one of Mr. Jones's 30c.p. dynamos. The F.M.'s are wound with No. 20 d.c.c. wire, and the armature ought to have been wound with ¼lb. of No. 20; but I wound it with No. 24 by mistake, and only got on ⅛lb. The machine lights one 10c.p. well, but only makes a 20c.p. red hot. If the armature was re-wound with ½ of 20, would I get any better results? Also, what kinds of lamps would suit this machine best—5c.p. or 10c.p.?—THOS. SMITH.

[61555.]—**Muriatic Acid.**—Through an oversight, a lot of iron was left in strong acid. A precipitate, blue crystals, formed on sides of vessel. The acid itself, so far as I can tell by trying with zinc, is neutral. Will someone tell me if it is possible to use it for soldering purposes, and how to make it so suitable?—ROB.

[61556.]—**Substitutes in Photography for Glass.**—Have any correspondents tried substitutes for glass for photographic negatives? I have seen little in the MECHANIC on the subject. I am about getting a camera, and shall be glad to know whether, by the aid of carriers, smaller negatives can be conveniently taken than the full size the back is constructed for?—IRIS.

[61557.]—**Vapour.** — Will any able correspondent kindly inform me what chemical change, if any, is afforded by a substance vaporised? I mean as regards the vapour given off by the heat. Say, for example, oil of sandal wood, or other of the essential oils. What, in fact, is the composition of such vapour in any one or more cases?—NO SIG.

[61558.]—**Metallic Paint.**—I see in last week's issue two correspondents give recipes for coating articles with copper; but Mr. Ray ends by saying that "the simple process of dipping in the sulphate solution gives a coat that will not stand handling." Is there any kind of metallic paint or lacquer of a copper or tin colour with which iron castings can be readily coated, and with a coat that will bear handling?—ORDERIC VITAL.

[61559.]—**Gold Paint.**—Can any kind reader tell me how to put a gloss on Bessemer's gold paint? I believe it can be done with some kind of varnish.—C. S.

[61560.]—**Engineering.**—A sum of £150 was paid to an engineering firm as premium for an articled pupil, to serve two years in fitting shops, two in drawing office, and twelve months in pattern shop, commencing with the fitting shops. The pupil (?) has now been there considerably over one year, and has little else to do but chip, chip, chip, all time. It must certainly be admitted that continuously chipping cast-iron cylinder flanges is scarcely calculated to impress anyone with the beautiful art of fitting. This is not the worst. If a pupil is seen noting the details of anything passing through the works, he is immediately dropped on and asked why he doesn't go on with some work. Now, what I want to know is, whether this is fair to pupils? Why is a premium required when the advantages accruing from it are little better than those obtained by apprentices who pay nothing? Can anything be done? It is a serious thing. I may add that there are several pupils at the work.—DISGUSTED.

[61561.]—**Gravitation.** — Will "F.R.A.S." or any other correspondent kindly state whether it is known what is the velocity of the influence of gravitation? I presume it is not absolutely instantaneous, but would possibly be comparable with that of light or electricity. I have never seen this stated in any work on astronomy or other book with which I am acquainted.—W. T. N.

[61562.]—**Mechanics.**—A particle whose mass is 4, moving with a velocity 12, meets and impinges directly on a particle whose mass is 8 and velocity 4; the co-efficient of restitution is 0·5. Find from first principles their velocities at the end of impact.—S. FORD.

[61563.]—**Torricelli's Theorem.** — A cylindrical vessel with a small hole at the bottom is 4ft. high, and is capable of containing four cubic feet of water. It is kept full, and it is found that four cubic feet of water flow out of the hole in thirty minutes. Find the size of the hole.—S. FORD.

[61564.]—**Instantaneous Exposures.** — TO S. BOTTONE AND "B.SC., PLYMOUTH."—I feel greatly obliged for reply, but will you kindly give the formula you use for this class of work? You say I ought to use the smallest stop; but I have found in using this stop (which is 3-16in. diameter, and lens 11in. focus for whole plates) that an exposure of about five seconds on ordinary plates for a view is correct, and a quick cap on and off with my medium stop, which is ⅝in. in diameter. This last must be much longer than that given with a slow shutter. My plates were certainly under-exposed, for two or three minutes passed after applying the dev. before any image appeared, and nothing but clear glass could be got out of the darker-coloured objects. Besides, I obtained better results with a rapid portrait lens, same aperture, and much shorter focus; but even with this lens my plates were under-exposed. I have had considerable experience in ordinary work, and I think I know what an under-exposed plate is. Something is wrong with my dev., or it requires a plate to be exposed longer than others, and so is not suited for this work. I thought when I began to use a R.R.S. lens I should have no trouble in taking instantaneous pictures; but I was greatly disappointed. Could I add anything to this dev. to get good results from quicker exposures, as I like it so much for ordinary work, that I don't like giving it up?—A. P.

[61565.]—**Daniell's Battery.**—I have an electric bell, which I wish, at a particular hour each day, to keep in action for a length of time. I have been told that Daniell's battery is more suitable for this special purpose than a Leclanché, because more constant though less powerful. I should be glad to have this statement confirmed if correct; or if wrong, to be informed which is the best battery to use. I find also that, in the Daniell's battery which I already possess, the sulphate of copper solution finds its way after a time into the inside of porous cell; cakes of a greenish-blue colour also form round the sides of the copper cylinder, and the top of the porous cell is covered with crystals, and becomes very brittle. If anyone would kindly give me information as to the cause and remedy of these things, I should be obliged. Daniell's cells, I believe, are used in the Post Office Telegraph Department. There must, therefore, be some way of keeping them in order.—LAMBDA.

[61566.]—**To Mr. Bottone.**—Will you oblige me by explaining the difference between series and shunt-wound field magnets, as I think of making a small dynamo, and if you could assist me in explaining how I could make it, so that I could get one or two different powers, say, from a strong physiological to a small electric light current, if I could do it by using different layers on the F.M.? I think of making it with the magnets 4in. high, 3in. wide, and ½in. thick.—A. DAY.

[61567.]—**Strength of Materials.**—Will any one show me a rule to find the proportional strengths of two pieces of square iron or two pieces of flat?—NOVICE.

[61568.]—**Gold.**—I have to set a piece of gold plate about 3in. by 2in. in the centre of a large gold dish. Now, the gold dish is of a rich copper colour, if I may use the term, and, being a young hand at the business, can any of "ours" tell me how I can give my piece of gold the same colour? As a further guide, the dish is something like the case of a genuine gold watch.—DUBLIN.

[61569.]—**Violin Maker.**—I have a violin stamped on the top of back, just under the neck, in old script type, "Grand Gerard." Is this a maker's name? If so, what is the probable age of the instrument? It is rather a flat model, colour orange to brown, has been varnished all over with a rather thin varnish, and has pointed *f* holes similar to those of Guarnerius.—A. B. C.

[61570.]—**Chemical.**—Will some chemist kindly inform me how to test the percentage of oxygen in BaO_2 as manufactured from BaO, by heating it at a certain temperature in oxygen gas? Is there any easy method by which I may test whether the whole of the nitric acid has passed off on converting barium nitrate into the oxide after it has been heated in a crucible to a white heat?—ENQUIRER.

[61571.]—**Organ Accordion.**—Would some correspondent kindly give me instructions how to make the reed pan or soundboard of organ accordion, and a few general instructions concerning the reeds, keys, and framework, and the cost of a set of reeds?—DERFLA.

[61572.]—**Wimshurst Machine.**—TO MR. BOTTONE.—I am making a Wimshurst machine after your directions in the "E. M."; but I am thinking of having two Leyden jars instead of the glass rods. Shall I be right if I put length of brass tube in jars to make metal contact with inside coating, and solder brass ball at proper height to carry the combs, and let discharging terminals fit in top end of brass tube? Will outside coating jars require connecting anyway?—LOUGHBURIAN.

[61573.]—**Microscope Lamp.**—I have a microscope lamp, made after the style of the Nelson-Mayall pattern—viz., a brass oil reservoir, sliding on the usual upright pillar, &c., and a copper chimney, through which the light is only allowed to pass through a narrow slit cut in the side and covered with the usual 3 by 1 glass slip which slides as usual in and out. Now, when I use the glass chimney to it there is no perceptible smell, but when

I slip the copper chimney on, then comes the unpleasant smell I have before alluded to. Now, what can be the cause of this? The burner is well made, and there seems to be plenty of ventilation, and the copper chimney is $1\frac{5}{8}$ wide inside at the bottom, and $7\frac{1}{2}$in. high, and well coated with plaster of Paris. A little advice from some of "ours" would oblige.—NEO-MICROSCOPICUS.

[61574.]—**The Calculus.**—In Ritchie's book on "The Calculus" (2nd edition, p. 12), occurs the following:—"If the side of a square increase uniformly at the rate of 3ft. per second, at what rate is the area increasing when the side becomes 10ft.? $1 : 2x :: 3 : 6x$. Hence the rate of increase is 6×10, or at the rate of 60 square feet per second." What does this mean? The area of a square having an 8ft. side is 64 square feet; that of a square having a 9ft. side is 81 square feet; that of a square having a 10ft. side is 100 square feet. The square with a 9ft. side, in passing into a square having a 10ft. side, has increased in area 19 square foot. How can it be said to be increasing on arriving at that size, at the rate of 60ft. per second? What has time to do with the increase? If the square lengthens its sides from 8ft. to 9ft. and 10ft., the increase of area is the same whether the change takes place in two seconds or in two months. In making the above remarks, I am not questioning the accuracy of the statement. I only wish to state that I cannot understand it, and ask some correspondent to furnish the explanation, which no doubt can be given, but which I have sought for in vain. The same or a similar example to that quoted from Dr. Ritchie's book occurs in at least two other works I have referred to. Hence I do not doubt its accuracy.—TYRO.

CHESS.

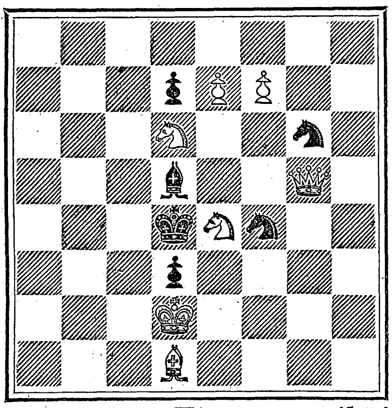
PROBLEM MXXVIII.—BY A. BOLUS.

Black.



White. [7 + 6

White to play and mate in two moves.

SOLUTION TO 1,026.

White.	*Black.*
1. Q takes B P.	1. P takes R (*a*).
2. Q-K 7.	2. Anything.
3. Q or Kt mates.	
	(*a*) 1. Kt takes R (*b*).
2. Q-Kt 6 (ch), &c.	
	(*b*) 1. Kt-Q 4 (*c*).
2. Kt (B 3)-K 2, &c.	
	(*c*) 1. Anything else.
2. Q-Q 6 (ch), &c.	

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,026, by Major (very fine and difficult), T. H. Billington (but variation 1. $\overline{\text{Kt-Q 4}}$ omitted), A. Bolus (ditto), and G. A. A. Walker; to 1,025, by Black Pawn, G. T. Stringfellow, Snowdrop, Avon, Hensing, A. Bolus, J. W. Hamill, T. H. Billington, J. J. Spence, Country Boy.

BLACK PAWN and H. Balson are thanked for problem and game.

COUNTRY BOY.—The number of variations is determined not by all the moves Black has at his disposal, but by the different ways White mates.

"THE PROBLEM ART."—This neat little work by Mr. and Mrs. Rowland will be found useful both to composer and solver. Some of the articles in it have been published before in the *Illustrated Science Monthly*. The main subjects are the art of solving and the art of composing. Much will be found here of considerable interest, and the remarks are illustrated by problems by various composers. To the beginner, and even the advanced student, the hints cannot fail to be of assistance in pointing out what to avoid and what to attempt; although practice, after all, is the great thing, and a systematic study of the works of the best masters. We should add that this book can be obtained from the authors, 9, Victoria-terrace, Clontarf, Dublin, and its price is 2s. 6d. The get-up is in Mr. Morgan's usual excellent style.—Simultaneous with the publication of this work is another of much more ambitious design by four of our greatest composers—Messrs. Andrews, Frankenstein, Laws, and Planck. This work, besides containing 400 selected positions by these masters, has seven opening chapters on the Chess Problem by Mr. Planck. Such a treatise as this has long been wanted, as of late years the character of the problem has undergone important changes. As Mr. Planck remarks, a good problem now must contain at least two fine ideas in appropriate form, and some tourney Problems (of which there are several in this volume that have won the highest prizes) contain six distinct themes. Thus the master-problem nowadays is a most elaborate work requiring great skill and patience to compose and, through its complexity, very difficult to solve. Mr. Planck's treatise is intended more for the advanced student, and thus it occupies ground quite distinct from the first book noticed. The steps we have to follow are further up the hill. It is not too much to say that this will become the standard textbook on the subject, and a work of the greatest value. Here again the solver is instructed how to solve—as a rule, to try quiet and apparently weak moves for the key, as such are characteristic of the higher class of problem. The functions of the composer and solver are, of course, to a certain extent opposed, and as the toil of the latter is made easier by exposing the methods of procedure, and taking, as it were, the puzzle to pieces, that of the former is rendered harder. It is like the question of guns and armour over again. What shall we arrive at at last? Mr. Planck remarks, with all the ardour of a devotee to the art: "It is this constant striving for a nearer approach to the impossible which produces such an irresistible charm for the modern problemist. His cry is ever Onward!—towards a goal which he knows he can never reach. . . . There are no bounds to the glorious forward march of the mind, so in his little field of research there is no end to improvement, no limit to everlasting discovery and advance." His observations (p. 79) on marking in problem tourneys are worthy of all consideration. They appear to us to tend towards the view we have always maintained that it is impossible to assign definite marks to a problem as a work of art, either with reference to the "ideal problem" or to others. We can promise the readers of this fine work a rare treat, and no chess library can be complete without it. It is published by Messrs. Cassell, and it is admirable in every respect.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

The following are the initials, &c., of letters to hand up to Wednesday evening, Jan. 26, and unacknowledged elsewhere:—

J. LANCASTER AND SON.—M. Glover and Co.—Barnett and Foster.—T. Beecham.—C. P. White.—W. F. Stanley.—Helix.—E. Shearer.—Joe Blain.—A. R.—Jacob George.—Herne.—C. R. O., Devon.—8-Day Clock.—A. Stanley Williams.—Cane Sugar.—W. G. Penny.—Country.—One in a Fix.—Tube.—Cathode.—Acier.—F. R. R.—H. P.—A. Collingridge.—En-Switched.—Another Reader.

CARBON. (See many replies in back numbers. Possibly three cells will answer for such lamps; but it depends on the resistance of the lamps, and that you do not state. See illustration on p. 561, No. 1117.)—NOVICE NO. 1. (It is not easy to make a small machine which will answer both as dynamo and motor satisfactorily; but you will find all necessary details for making either in back volumes. Look through the indices of the last six, say.)—COLLIN. (For directions for making small electro-motors, see pp. 257, 274, 315, Vol. XL., and the indices of recent volumes.)—ALFRED. (Pipeclay will answer, but is scarcely porous enough. Flower-pots are rather too porous. You want a clay that is between the two in degree of porosity. 2. The other questions have been answered many times. They would occupy space, is one reason. The coke and peroxide should be intimately mixed. No one can say. The box must be thoroughly dry, and the glue applied hot.)—IGNORO. (You can use a layer of slag wool or felt between the joists and the wood ceiling, and the usual pugging between the joists. A filling of sawdust would be better than pugging. 2. Spring-heeled Jack has been heard of; but the exact method he adopted of fitting springs to his boots has not been described. You should make some experiments.)—WILLING TO WORK. (You should procure some of the interlinear translations of the Roman authors.)—F. H. R. (We should not use sugar in a steam boiler, for common soda will answer as well; but in the case of your kitchen boiler the best way would be to take out as much of the lime as possible before putting the water into the boiler. You can do that by adding a "cream" of lime and water, and stirring well. See indices.)—AMATEUR ARTIST. (The enamel must be baked or fused on, as frequently described; but for baths you can use varnish paint, cleaning the iron well.)—YOUNG BEGINNER. (What has the circumference to do with it? If not marked, you must test it to ascertain the candle-power. Suitable batteries have been described over and over again.)—THANK YOU. (See answer to "Collin" above.)—JIRK. (Full directions have been given many times. Look over the work again. Perhaps it is not connected up properly. 2. Surely you should procure one of the cheap handbooks of photography. We are afraid you will have to use more than one plate to obtain a "portrait": you certainly will have to use a plate for each single portrait.)—J. S. P. H. (See recent numbers.)—W. H. J. (One coil is enough. Start from centre, and draw it nearly off at each end, returning to centre before stopping current. A short coil of stout wire is sufficient. Hard shear steel. Answered in most of the textbooks, and several times in back volumes.)—A. J. G. (There are several methods of cleaning furs; but perhaps the simplest is to rub in moist bran with a bit of flannel, and afterwards dry bran with a bit of muslin. Then brush well, and finish by wiping down with a rag dipped in benzoline.)—C. KEMP. (Mineral naphtha will dissolve both pitch and guttapercha. The latter is also dissolved by chloroform, benzol, bisulphide of carbon, and rectified turpentine. Chloroform is rather expensive, and there is no cheap sweet-smelling solvent.)—J. W. B. (Almost all the low-priced inks are made without galls. You will find many recipes for inks and writing fluids in back volumes.)—GAUGE. No room for puzzles of that kind. 2. For an epitome of the history of the wire-gauge, see No. 778. We can quite believe that no one seems to know where the original standard B.W.G. is kept. If there ever was one, it has been lost.)—ROBERT PICKLES. (See Hints No. 5. Lacquer; but nothing except frequent applications of "elbow grease" will keep it bright if in use.)—CANALS. (We have not the slightest idea. As so few canals have steamers running on them, it is doubtful whether there is any fixed salary for an engine superintendent.)—ISAAC LEYLAND. (Messrs. Trübner, Ludgate-hill, E.C.; but they do not supply single copies. You must subscribe, we think, for a year. You could try the American Exchange, Charing-cross, W.C.) — IGNORAMUS. (You must either keep it polished, or relacquer. If the latter, better get it done for you.)—A NEW READER OF THE "E.M." (Do you mean French polishing, or simply oil-polishing? Fill in the grain with size, or better, with clean fat and a little whiting stained to suit, and put on some French polish. Or size, and coat with white hard varnish.)—LEAN MAN. (No space for such experiences. Starchy and saccharine foods will aid in the production of fat.)—J. B., London. (See illustrations in back Nos. (986, 989, for instance), or procure one of the manuals—say that issued by Mr. Eldridge, 54, Murray-street, Hoxton. 2. In one form the steam from the wood is condensed by a series of cold-water pipes, and runs into a trough; but if hot dry air is used, that carries away the moisture.)—CYMRO. (If they inherit under the father's will, no probate is required, but succession duty must be paid. If the widow made a will, probate must be taken on that.)—T. M. P. (We do not understand that there is any question of depositing copper on a gelatine mould in the letter referred to. A gelatine photo. is prepared in the well-known way, and a mould is taken from that, the copper being afterwards deposited on the mould. For the other method you must wait and see whether the query will be answered.)—YOUNG ENGINEMAN. (Procure a glass tube, not less than a quarter of an inch internal bore, and 34in. or more long. Close one end in the blowpipe flame, and fill the tube with mercury. Place the thumb on the open end, invert, and immerse in a cistern of mercury before removing the thumb. If both mercury and glass tube are clean, the former will "fall" and stand at the height due to atmospheric pressure.)—X. (Must explain what is meant by "fluid ink eraser." Perhaps it is a solution of chloride of tin.)—GYPSUM. (Much the same as marble. Pumice first, if necessary; then whiting mixed with soap and water, and finally dry flannel. If a high polish is wanted, use a paste of sifted slaked lime and water, and finish with French chalk and putty powder.)—REV. W. MERRELL WHITE. (Cannot be done without an elaborate analysis. See an answer by Mr. A. H. Allen to a similar question in No. 1060, p. 434.)—S. BRIDGETON. (There is nothing to prevent you, or any one else, advertising as a "consulting engineer"—no examination to pass or certificate to obtain.)—A. M. C. (That has always been a difficulty, and it is impossible to advise without details. Sir H. Bessemer's gold paint was kept a secret, and possibly a firm of manufacturers might purchase your secret; but there is always a risk. If a patent is obtained, those who use the process secretly run a great risk of having their proceedings betrayed. What advantage could be gained by inserting such a query?)—YOUNG WIFE. (It is of no use to scrub it; but it may be possible to plane the stains out, though that is doubtful. Why not have it stained a dark colour and polished?)—INKPOT. (No one can do more than guess, and we suspect that the magnet is not near enough to the plates. Any one may make and use a patented invention for experiment; but he must not use it for profit or even for mere amusement.)—E. A. B. (Better buy such varnish; but there are several recipes in back volumes. 2. The 100-ton gun is 32·65ft. long, with a bore 30·25ft. long, and a calibre of 17·72in. Those are the dimensions of the original gun tried at Spezia in 1879. Later examples have slightly different dimensions—notably in the powder chamber, which is of greater calibre than the rest of the bore.)—J. C. H. (You will find something about the subject in recent numbers, and all that can be said about it in back volumes. It is a subject for papers read before learned societies.)—A. P. BOWER. (We do not undertake to deliver any subscription copies, and we fear the Post Office will in no way help to second your benevolent intention.)—V. FALKNER. (Thanks; but we think it is hardly worth engraving, especially as the description has appeared elsewhere so long ago. It is very ingenious; but as you say, others are working in the same field, and we fear your labour will not bring you much reward.)—ACIER. (Better ask the editor of the *Lancet*. We are not responsible for recipes quoted from other journals.)—J. C. D., Liverpool. (Cheaper to buy, by far; write Hill and Co., 46, Essex-street, Strand, W.C.)—ONYX. (It is safer, of course, to wait till the patent is sealed.)

IT has been computed that about 35,000 newspapers are published in the whole world, or one for 28,000 inhabitants. Of this number 16,500 are in English, 7,800 in German, 6,850 in French, 1,600 in Spanish, and 1,450 in Italian.

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, FEBRUARY 4, 1887.

EVANS'S BOOK ON ORNAMENTAL TURNING.

[SECOND NOTICE.]

FURTHER perusal of this volume confirms the high estimate which we formed at our first cursory examination of its contents; consequently we propose in this second notice to enter somewhat more fully into details, adding (by the author's permission) one or two illustrations borrowed from its pages. The first is a new design of universal cutting-frame (Fig. 122), which will probably be acceptable to some of our readers who are adepts at making as well as using lathe apparatus. It will be readily understood that in all such cases as the present cut gears are absolutely indispensable, and the fitting of all revolving spindles must be carried out with such accuracy as to prevent all jar or vibration, which is fatal to good work. The spindle is here forged in one piece with the arm, and bears against a collar $1\frac{5}{8}$ diam. to give greater firmness and solidity. The bearing of the spindle which carries the tool is very similar to that of a drilling instrument, so that all vibration is checked at this part. The tool, when fixed with the spindle in a vertical position, points to the axis of the shaft which passes through the square stem, and when set for work to be cut at the centre is identical with the axis of the lathe mandrel. There is great ingenuity displayed in this design, and many amateurs of known skill in ornamental turning testify to its excellence. The only possible question that can arise as to its efficient working is that which is here answered satisfactorily by those who have given it an extended trial—viz., the possible tremor given to the tool by toothed gearing. Badly cut gears or loose fittings do undoubtedly cause vibration; but this is equally true of all gearing unskilfully manufactured. If well made, and the teeth formed with scientific accuracy, the motion should be perfectly smooth and true, free from backlash and "shake." The vibration of gearing arises, no doubt, from each tooth *striking* that with which it comes in contact, causing, like every other blow, reaction or rebound; and nothing will prevent this but such a form of tooth and close (not tight) fitting as shall cause successive teeth to take up the work of their predecessors before the latter absolutely escape from their labours. True, none but a skilled workman can carry out this; but such alone, we suppose, would undertake the construction of first-class lathe apparatus.

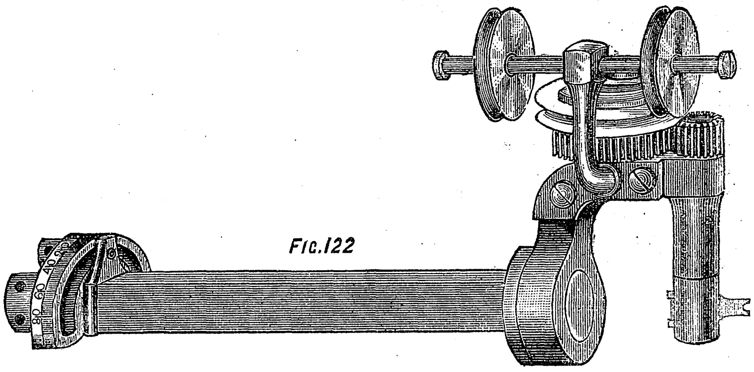


FIG. 122

We reproduce Fig. 169, because it gives an excellent sample of the general engravings; but the reproduction is not, of course, equal to the original, because the latter is executed upon superior paper of polished surface. Ours represents the work-a-day suit, the other the Sunday coat—each, therefore, claiming some merit peculiar to itself. The engraving shows the spiral apparatus as arranged by Mr. Evans, who reverts to its original position at the back of the headstock; but with special fittings, which remove the drawbacks which were inseparable from earlier arrangements. A novel and ingenious dividing apparatus has been introduced by Mr. Evans, for the details of which, however, we must refer the reader to the book itself. It is certainly more convenient to get the radial arm and train of wheels further away from the operator as well as from the chuck and the work. The chuck, moreover, has not to carry the first wheel of the train, and again by means of a very perfect universal joint, the motion can be applied directly to face-work without the usual additional standard and bevel wheels. It is a regrettable fact that we are unable to reproduce the autotype plates; but it is better, and fairer to the author, to refer inquirers to the volume itself. Plate 5, nevertheless, strikes us as a specially beautiful design in drilled work. It is not put forward as a specimen which from the difficulty of reproduction need deter the amateur from attempting to copy it, for, as Mr. Evans says, it is chiefly a question of patience. It is, in fact, simple drilling; but the result is very lovely. The more ambitious amateur, who is better supplied with lathe apparatus, will probably reproduce in preference an elliptic ivory casket, and a magnificent candelabrum of similar material, which will exercise his skill no less than his perseverance. Many a reader will feel like a street arab, however, gazing at the delicacies in the pastry-cook's window, sadly feeling that they are to him forbidden luxuries, the "oof bird" not having hatched for him the needful egg. But here again Mr. Evans comes to the fore with explicit directions how to make several of the simpler appliances for ornamental turning. Indeed, most of the apparatus is explained so as to assist, or completely instruct, a reader who knows how to turn and can use a file; and our own pages have often testified that the author of this book does not belong to that narrow-minded class of skilful operators who selfishly keep their knowledge to themselves.

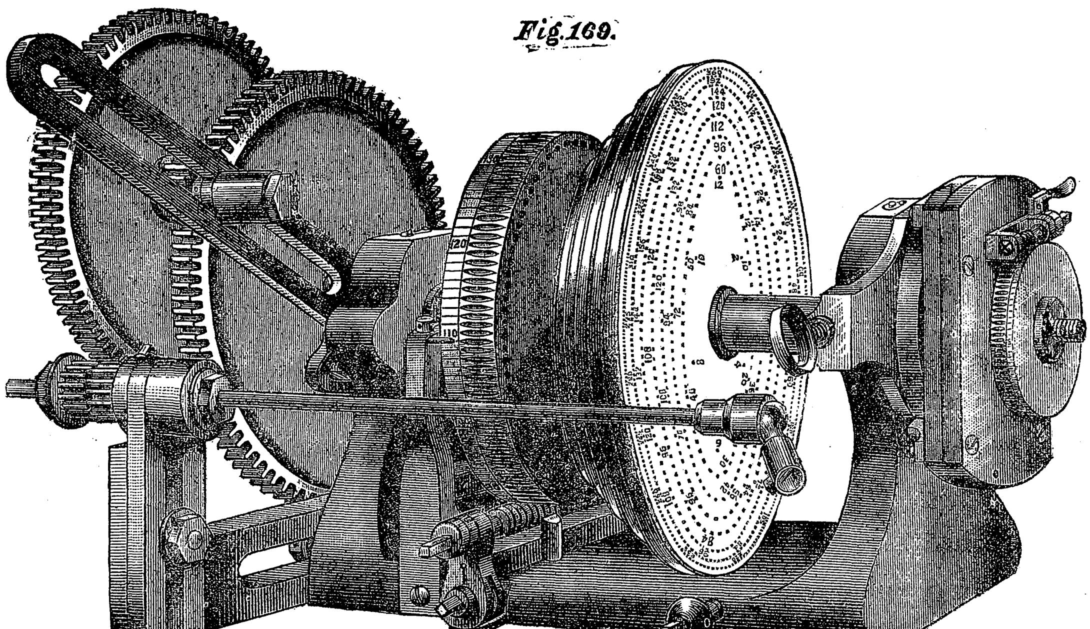

Fig. 169.

We noticed a remark in a letter, that the radial drilling of a division plate on Mr. Evans's plan would only affect the zero points of the several circles. Surely this is not so. If in each row the holes are equidistant, the series started on a curve will so continue, and we might, in fact, take any set as zeros. Mr. Evans, however, gives another plan which appears to us very excellent. The index is pivoted to the top of a pillar on the further side of the headstock, and lies tangential to the circles. The peg which enters the holes is thus close to the operator, and very clearly visible. Here, again, radial

drilling of the holes is successfully carried out. The automatic index is fully described, but we do not feel it necessary to give the illustration; and, indeed, we have already perhaps lingered lovingly, but almost too long, over this admirable book. We observe that subscribers have in some instances failed to see our advertisement, in which the volume is priced by the author at a guinea, with 6d. extra for postage. Autotype plates are costly always, and those contained in this book leave nothing to be desired.

THE THEORY OF MACHINES.—I.

By Francis Campin, C.E.

Modification of Power by Mechanical Elements.

In order to acquire the knowledge necessary to render us competent to design machines that shall give satisfactory results, we must carefully investigate the characteristics of the various phenomena of "force" as elucidated by rational and experimental research, in connection with various mechanical appliances devised to vary the conditions under which they are exhibited.

Into the intrinsic nature of force it is not our business here to inquire; but we may satisfy ourself with the fact that its total quantity is constant, it admits of change from one form to another (as heat to work, electricity, &c., and the converse); but it can neither be created nor destroyed by human means. It may further be laid down as an axiom that matter under all known conditions, whether at rest or in motion, is subject to the action of natural forces.

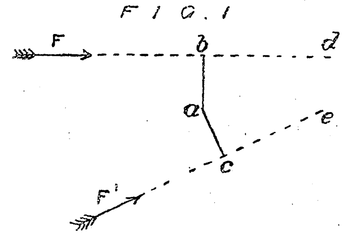
If the forces acting upon a body are in equilibrium—that is, if action and reaction be equal and opposite, the body will be at rest; but if the forces be not in equilibrium, motion will ensue in a straight or curved direction according to the relations of the forces in operation.

By the term "a force or pressure" is indicated a given *intensity* of force acting in the direction of some given straight line, and the action of one such force unopposed will produce motion in a straight line; the concurrent action of two or more forces not in the same straight line may produce motion on a curved line.

A force acting about a point as a centre, multiplied by the least distance of its direction from that point, gives as product the "moment of the force" about such point; thus, if a pressure of 100lb. act on the tooth of a wheel (tangentially to the wheel) 2ft. in radius, the moment will be = 100lb. × 2ft. = 200ft.-lb.

In Fig. 1 let F F′ be two forces acting about a common centre a. Produce the directions of

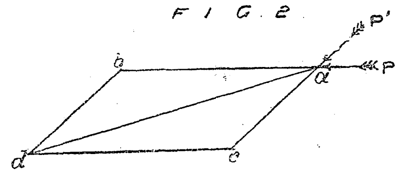
FIG. 1



the forces to d and e respectively, and from the point a draw $a\,b$ and $a\,c$ at right angles to F d and F′ e respectively; then will $a b$ and $a c$ be the least distances from a to the directions of the forces F F′, and the moments of the forces will be F × $a\,b$ and F′ × $a\,c$; if these are in equilibrium, then F × $a\,b$ = F′ × $a\,c$; therefore, $\frac{F}{F'} = \frac{a\,c}{a\,b}$, or the intensities of the forces are inversely as their distances from the centre about which they act. If motion of the points b and c occur, their velocities will be as $a\,b$ to $a\,c$, and therefore inversely as the forces. Hence calling one force the power and the other the resistance, they will be to each other as their virtual velocities, inversely. If motion does occur, "work" is done; thus 50lb. acting against a resistance through 10ft., 500ft.-lb. of work is done, and as work cannot be created, it is evident that that done on a machine must be equal to that expended on the resistances, and the distances passed through in a given time by the driving and working ends of the machine will be (friction omitted) inversely as the intensities of the forces.

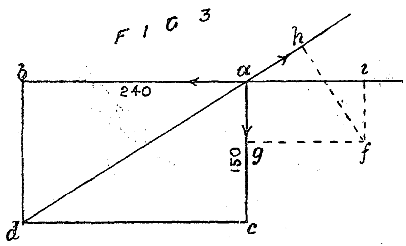
We will now consider the action of two forces at an angle to each other upon a given point. In Fig. 2 let P P′ be two pressures acting at

FIG. 2



the point a in the directions shown by the arrows, produce the lines of direction, making $a\,b$ and $a\,c$ represent the forces P P′. $a\,b$ and $a\,c$ represent the distance through which the forces are each capable of moving a body at a in one second; then the two acting concurrently will move it along $a\,d$, the diagonal of the parallelogram $a\,b\,d\,c$, for if P acted first it would move the body to b, and P′ then acting parallel to its own direction would move the body from b to d, the two forces P and P′ may, therefore, be replaced by a force represented in intensity and direction by $a\,d$, which is termed the resultant of the two forces. The accuracy of this principle of the "parallelogram of forces" may be verified by the principle of moments. In Fig. 3

FIG. 3



$a\,b\,d\,c$ is a parallelogram of forces in which $a\,d$ is the resultant of the forces $a\,b$, $a\,c$. From any convenient point f draw perpendiculars $f\,g$, $f\,h$, and $f\,i$, to the directions of the forces and their resultants; then if the forces $a\,b$, $a\,c$, are equilibrated by $a\,d$, the same should obtain with their moments about f.

The pressures are taken to a scale of 200lb. per inch, and the distances from f are measured in 200ths of an inch; the values are $a\,b$ = 240lb.; $a\,c$ = 150lb., and $a\,d$ = 284lb.; the distances $f\,g$ = 123; $f\,h$ = 118; and $f\,i$ = 63. The moments of the two first forces are 240 × 63 × 150 × 123 = 33,570; and that of the third 284 × 118 = 13,512. Considering the small scale, these figures approximate closely, and so prove the accuracy of the principles involved; but the student should plot examples to a larger scale, using a vernier or a diagonal scale for measuring.

The British units for velocity are feet and seconds, and the measure of force is the momentum it communicates to a body in a unit of time, so a unit of force would be that which, acting upon 1lb. of matter, would produce in one second a velocity of 1ft. per second.

The force of gravity produces in one second a velocity of 32·19ft. per second; but for practical purposes we may take it as 32·2ft. in one second. If, then, a body at rest commences to fall freely, at the end of t seconds its velocity v will be $v = 32{\cdot}2\,t$. The height, h, through which a body will fall in a given time, will be equal to the time multiplied by the mean velocity; if the body be acted on by a *uniformly* accelerating force, commencing with no velocity, then the mean velocity for the whole time of fall will be $\frac{32{\cdot}2\,t}{2}$, and the height fallen through $h = \frac{32\,.\,2\,.\,t}{2} \times t = \frac{1}{2}\,.\,g\,t^2$, where g is used to express 32·2, the value of gravitative attraction. But $v = g\,t$; $\therefore\ t = \frac{v}{g}$ and $h = \frac{1}{2}\,g\,t^2 \times \frac{1}{2}\,.\,g \times \frac{v^2}{g^2} = \frac{v^2}{2g}$ whence, also, $v = \sqrt{2\,.\,g\,h}$.

If the body does not fall freely, but against a resistance, it is capable of doing work equal to its weight W multiplied by the height of its fall, or = W h. If, however, the body does fall freely, the work it is capable of doing will be *accumulated* in it, and will bear a certain relation to its velocity at any point in its fall. Replacing h by its value in the expression W h, and calling A = the accumulated work, A = W h $= W \times \frac{v^2}{2g}$, and thus is found an equation giving the accumulated work in any moving body of which the velocity is known, *regardless of the source of power.*

The work done upon a machine divides itself during its transmission into either two or three parts: the first, that which is absorbed by friction and other useless resistances, known as prejudicial resistances; second, that which is accumulated in accelerating the velocity of the various parts of the machine; and third, that which is expended in doing useful work.

When a machine is started from rest it must, in its various elements, accumulate work until it has attained its normal working velocity, after which, while the velocity and resistance remain uniform, the driving-power will be divided only between the prejudicial and useful resistances. It is evident that there must in every machine be some prejudicial resistances, and therefore, economically speaking, some waste of power.

If a machine is intermittent in its execution of work, then the applied power will be accumulated for some definite period in the moving parts, and subsequently given off at the working end of the machine, so that there will be cycles at the commencement of each, of which the velocity will be the same, and all the power taken up during one cycle will have been divided between the prejudicial and useful resistances at its termination.

The work done by the machine on useful resistances divided by the work absorbed at its driving-end is the co-efficient of efficiency of the machine.

Mechanical inventions are not to be regarded as discoveries, for they consist merely in the arrangement of known elements, according to equally known principles, in such manner as to obtain a specific result, and it is an acquaintance with these principles that will enable an intending designer to expeditiously determine whether or not a proposed end can be attained by means of mechanical contrivances.

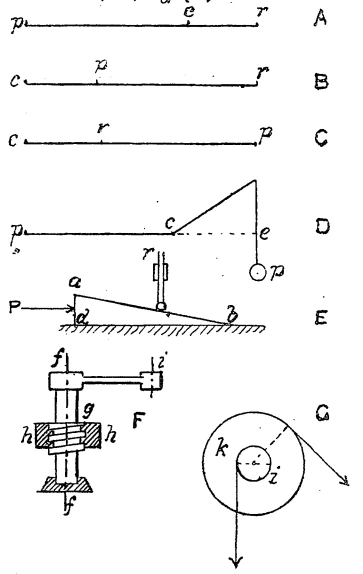
There are movements that cannot be imitated mechanically, such, for instance, as stitching fabrics together. In hand-work, the needle passes *completely through* the two pieces to be joined, re-entering at some other place, whereas in the sewing-machine the needle must return through the opening it has made in entering. Here is a very familiar case where the natural action being unattainable, a mechanical one has been designed which serves as a very good substitute, and from this it may be taken that the designing of an apparatus is not to be given up as hopeless because the movement which has been customarily used is not obtainable.

In the majority of cases an invention will be evolved by the co-operation of two classes of minds: the one finds out what is required to be done, and the other finds out how to do it, and, as a matter of fact, a want must arise for an invention to be of any use. If nothing but a modification of power is required, we have merely to proportion our machines according to the principles previously explained, as will appear from the following examples of simple machines, which, however, we shall here deal with only in regard to the proportions necessary to bring about the required changes, as the determination of sizes necessary to enable the various parts brought into action to resist the bending or breaking strains to which they will be subject is distinct from, though dependent upon, the general dimensions now occupying our attention.

It has been the practice in the older text-books to separate the various simple machines, levers, screws, wheel and axle, inclined plane, &c., to such an extent as to lead the student to the idea that each had a separate theory, and that each theory must be *learnt* independently of the others, and thus the whole matter has been complicated and perplexed; but it will here be seen that the general principles apply indifferently to all of them. For the present, friction will not be taken into consideration.

At Fig. 4 are shown diagrams of the mechanical elements of which most machines are built up. A, B, C, and D are levers, E an inclined plane or wedge, F a screw, and G a wheel and axle. In each case p is the point of application of the power of r the resistance. Let P and R represent the intensities of the power and resistance respectively; c is the fixed centre or fulcrum upon which the lever moves. The pressures are supposed to act at right angles to the length of the levers.

FIG. 4



Now it is evident that in the cases of A, B, and C the relative virtual velocities of the points p and r will be in direct proportion to their distances from c, those distances being the radii of the arcs in which they would move. If, then, the pressures are in equilibrium, it follows that $P \times pc = R \times rc$; so that if any case can be settled by one or other of the expressions, $P = R \times \frac{rc}{pc}$; $R = P \times \frac{pc}{rc}$; $rc = pc \times \frac{P}{R}$; and $pc = rc \times \frac{R}{P}$.

In the case of the bent lever, shown at D, the power does not act at right angles to the arm of the lever upon which it is exerted; draw, therefore, ce at right angles to the direction in which P acts, then by replacing pc in the above expressions by ec, this case may also be solved.

At E is an inclined plane on which the power is applied in a direction parallel to db; da is the vertical height, and ab the upper surface of the plane; the resistance is applied through a rod, r, which is capable of moving only in a direction at right angles to db; the ratio of the velocities will then be as db to da and $P + db = r + da$.

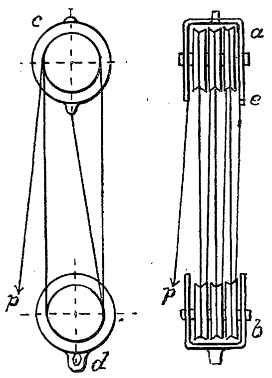
At F is shown a screw, turned by a handle, fi, ff being a line passing through the centre of the screw longitudinally, and i being the point of application of the power P; g is the screw upon which is fitted the nut h, so secured that it cannot revolve with the screw; to this nut $h\,h$ the resistance R is applied. It follows from this arrangement that when the screw is turned the nut will be raised or lowered according to the direction of revolution.

A screw is formed by wrapping an inclined plane around a cylinder with its base at right angles to the axis of the cylinder, the distance measured parallel to the axis, from the centre of the thread to the centre of the next turn is called the pitch of the screw, and is the distance the nut will be raised or lowered by one revolution of the screw Let D = the pitch of the screw, the ratio of D to the circumference of the circle of which fi is the radius will be that of the velocities of i and $h\,h$, hence $P \times 3{\cdot}1416 \times 2fi = R \times D$; $P = \frac{R \times D}{6{\cdot}2832 \times fi}$.

At F is shown a wheel and axle: the power P acts in the direction p upon the periphery of the wheel k, and the resistance acts in the direction r upon the periphery of the axle l; the ratio of the velocities in this case will be that of the radii of the wheel and of the axle; so if x = radius of wheel, and y = radius of axle, $P \times x = R \times y$, which equation can be transposed in like manner with the previous ones to suit any form in which the problem may present itself.

In Fig. 5 is shown another arrangement exhibiting a number of pulleys termed a block and fall, ab is a side, and cd a front view.

FIG. 5



The top block a or c is firmly fixed to some suitable beam or other support, and from it is suspended by chain or rope the fall or bottom block b or d. The pulleys in each block turn freely upon a fixed pin secured to the cheeks of the blocks, and the chain or rope runs freely over them; the power is applied at the free end p of the rope, which, after passing over the pulleys in the top block and under those in the bottom one, is fixed at e to an eye in the top block. The resistance acts at r.

It will be seen by inspection that to raise the lower block 1ft., 6ft. of rope must be pulled over the end top block, so that each of the six lines of rope running between the blocks may be shortened by 1ft.: hence the ratio of the velocities of the points p and r will be represented by the total number of pulleys. Let this number = N, then $P = \frac{R}{N}$; or $N = \frac{R}{P}$.

The above are most of the simple forms of mechanical movements for varying the relations between pressure and velocity in a given quantity of work; but others, and those of more complicated descriptions will be treated in subsequent articles.

THE AMATEUR WORKSHOP.—XXXIII.

Smith's Work.

THOUGH none but a professional smith could hope to undertake elaborate works in wrought iron and steel, yet many simple jobs can be done with a very moderate amount of practice, such as the bending, drawing down, upsetting, shaping, and welding of the plainer kinds of work. I shall, therefore, as I did with the brass-foundry, devote a couple of articles to a condensed description of the various smith's tools and their uses, together with a few practical hints on the management of iron and steel.

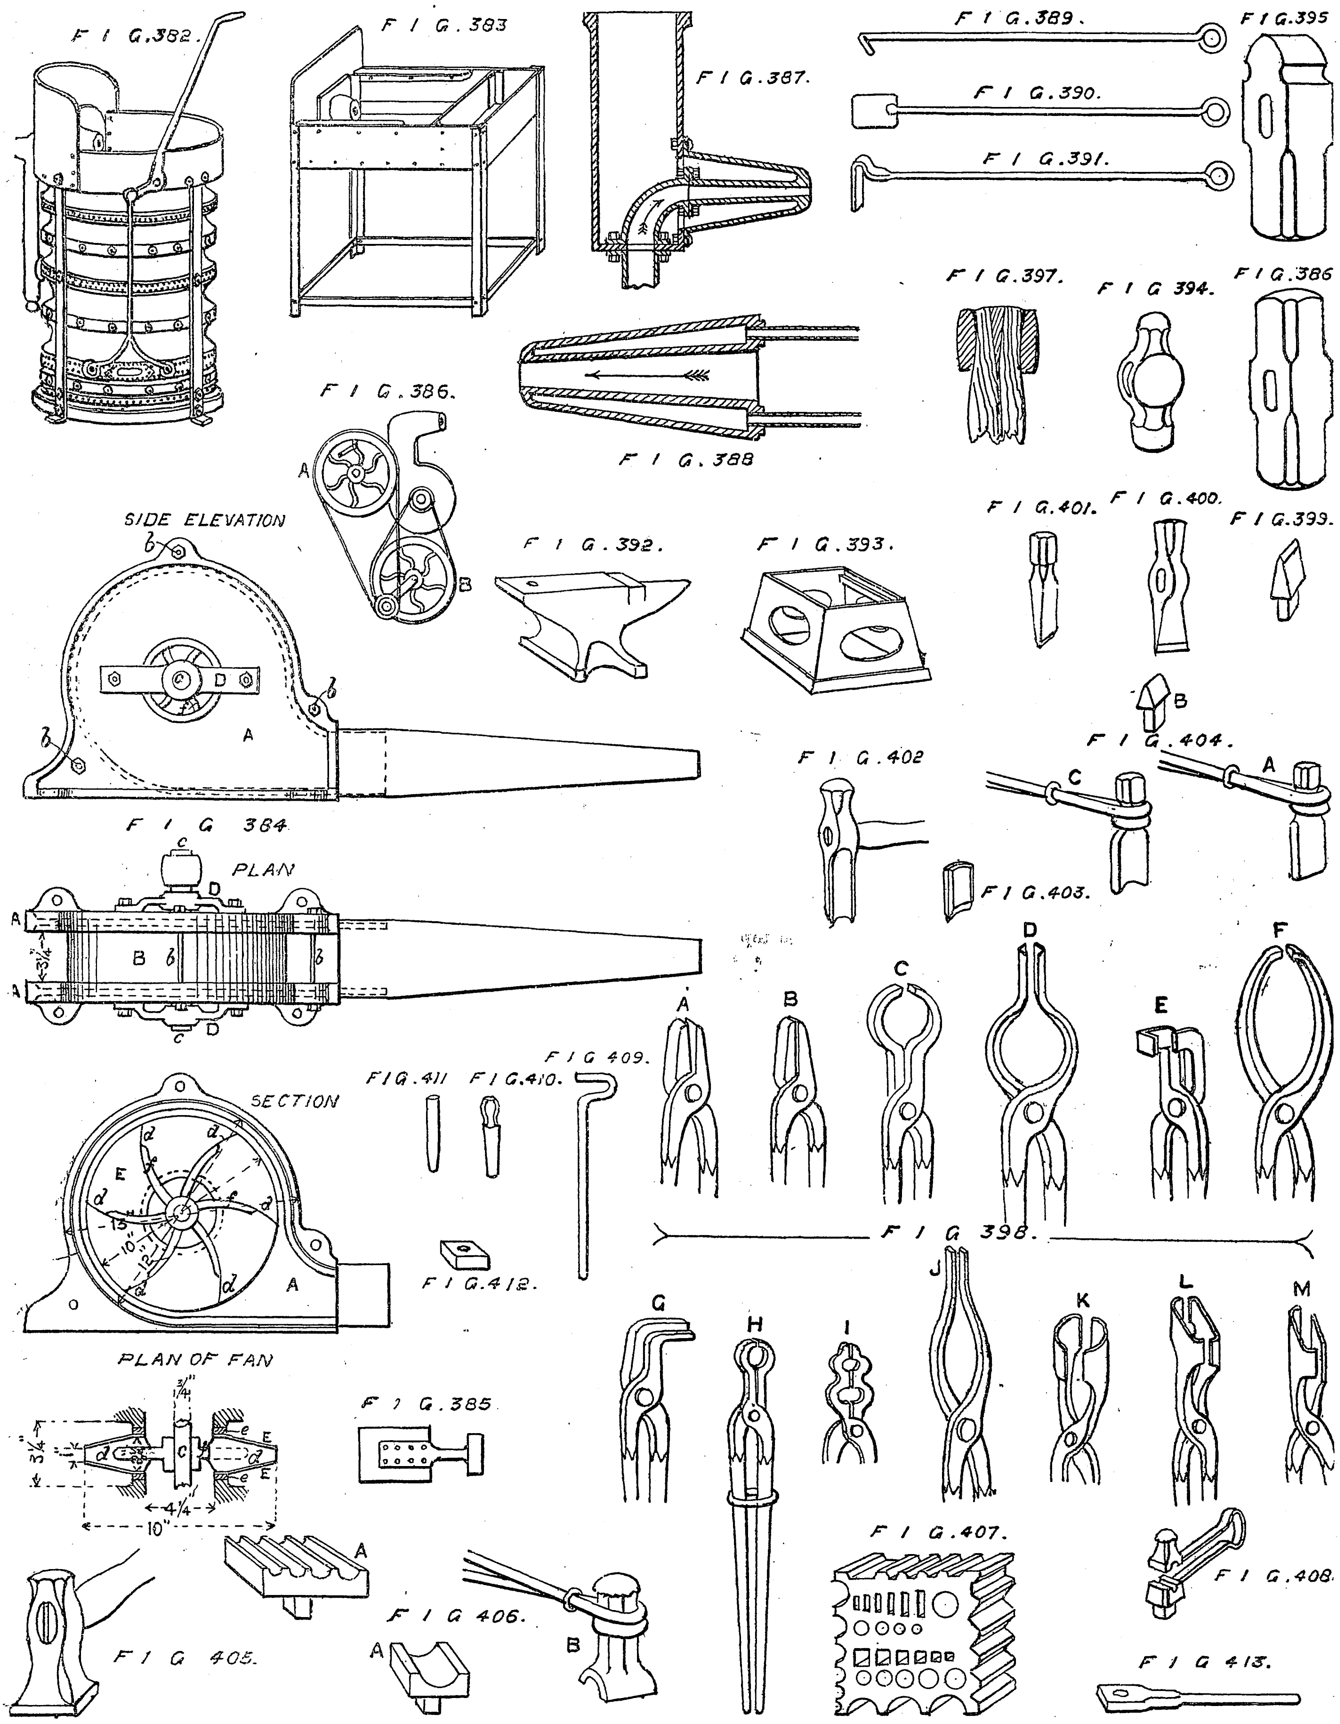
In a small shop an ordinary forge would be rather cumbersome, hence one of the small portable forges would be preferable to a mass of brickwork and iron, if it were not for the difficulty of carrying off the smoke. If the forge is to be in a closed building there must be a hood and chimney; if, on the other hand, it could be placed without the building, protected by a lean-to roof, a portable rivet or similar forge would be lighter and less expensive. The common brickwork type is so well known that I have shown two of the portable types in preference, and these are in keeping also with the amateur appliances and tools already described. The circular bellows in Fig. 382 are either of the single or the double-blast type, the latter giving a continuous current of air, but being also the more expensive of the two. Forges with 16in. bellows are the smallest made, and either these or 18in. would be the handiest for a small shop. A light framework of bar iron supports the circular hearth. The circular bellows are carried beneath, and are worked by the handle, levers, and rocking shaft, the blast being conveyed through the bend pipe into the back of the hearth.

The ordinary fixed forge is built of brick or stone. The hearth bricks simply inclose a hollow space which is filled with cinders, and upon which the fire is laid. The hearth back is of brick or stone, faced at its lower portion with a plate of iron through which the tuyere passes, and pierced at its upper portion with a square hole leading into the chimney. The chimney need not be long, its function not being the production of blast, but only of a sufficiency of draught to lead away the smoke. The face of the hearth for a few inches inwards from the edges is usually covered with a sheet of cast or of wrought iron for the sake of protection to the bricks. Two troughs occupy the front of the forge: a coal bunk, and a slake or water trough, the two often being made in one casting.

About the cheapest forge which can be made is that shown in Fig. 383, and one which any amateur could construct at a low cost, and with very little trouble. It can be employed out of doors, or placed indoors under a hood and against a wall leading into a chimney. Angle irons for the supports, flat bar iron for the horizontal stretchers, and sheets for the hearth and coal bunk are all that are required. The bearing surface of the angle iron will keep the structure from rocking, but if there is any tendency to unsteadiness when working the bellows a diagonal brace on each framing will prevent it. The blast may be taken from long bellows placed underneath, and worked by means of a lever handle, set conveniently behind the hearth back, but keyed to a rocking shaft which moves in bearings bolted to the under side of the hearth plate. The rocking shaft passing thus underneath to the front of the forge actuates a lever and connecting rod, completing the connection with the bottom board of the bellows. Or the blast can be taken from a blower at the back, either with single or multiplying gear. A small forge of this type may measure out and out, 26in. long, 22in. wide, and 30in. high. The angles may measure 1½in. × 1½in. × ¼in., the bar stretchers 1¼in. × ¼in., and the sheets about ⅛in. thick.

The supplying of the blast is effected either by means of bellows of circular or long pear-shaped form or by fans or by blowers, and in these matters the purse and the convenience of the user would be consulted. Bellows are worked by a handle and rocking staff, and attached to the forge, or distinct therefrom, according to convenience. A fan is preferable to bellows, and is worked by hand or foot, or power, but should be driven with multiplying gear to get up the speed. In factories a single fan worked by a belt from the engine supplies blast to a range of forges; a throttle valve under the control of the smith regulating the passage of the blast to each forge. Numbers of small forges are now sold very cheaply fitted with fans, or with Root's blowers, so that the old-fashioned leather bellows seem to be doomed to ultimate extinction. A small fan is shown in Fig. 384. The cheeks A are of cast iron grooved to a bare ⅛in. deep, a, to take the strip of sheet iron or brass B, which is cemented in with white lead and clamped together with bolts b, passing between the sides. The fan spindle c is carried in bridge-like bearings D, bolted to the sides of the cheeks, and the fan itself is composed of dished sides of sheet iron or tin E, between which the vanes d, are soldered. The dished sides are soldered to brass rings, e, which run against the inner faces of the cheeks. The vanes or blades are also soldered to the curved ribs f on the central boss, made of gunmetal. The actual fan requires to be nicely balanced owing to the high speed at which it rotates. The fan sides are each furnished with a central hole to admit the air. Instead of flat cheeks, two castings can be made with curved outlines, and bolted together with a central outside flange in the manner so familiarly known in foundry and other fans; but this means the making of two rather troublesome half patterns. The form of blade used in the common old-fashioned fan is shown in Fig. 385, but it is noisy. It is easy to make, the blades revolving within the outer casing, and as close to the sides without actually touching them as possible.

By multiplying gear, we mean some arrange-



-ment by which the proper speed of a fan can be imparted without excessive labour at the hand wheel. A hand wheel driving direct to the fan pulley will do, but with multiplying gear smaller wheels and less work will effect the same results. The perspective view (Fig. 386) illustrates this gear, the relative positions of the wheels varying as best adapted to the forge itself, and, of course, a treadle can be substituted for the handle. As drawn, the wheel A would be to one side of the forge clear of the hearth, its bearing being bolted to the hearth back, the bearings of the other wheels being bolted to the stretchers underneath the hearth. 10in. would be a good size for the wheels A and B. Bands are preferable to ropes running round grooved pulleys, since the latter properly require tightening gear for alterations in length due to temperature.

There is also the tuyere or tue iron to be considered, its function being the conveying of the blast to the fire. The nose of a tuyere would rapidly burn away, and does inevitably burn in time; but its destruction is retarded by the formation of a water chamber behind and around it, a current of cold water being made to circulate by convection within a conical cylinder through which the blast pipe passes, the whole being attached to a cistern or "water bosh." Fig. 387 shows this, the more modern type, in section, and Fig. 388, a section of the older tue iron, made either in cast or in wrought iron. These are illustrative, however, of the tuyeres used for large forges; but the small forges here figured are not provided with a water tuyere, because they are not subject to so fierce a heat as those of larger dimensions, and they are used intermittently. The nozzle which receives the blast pipe is, therefore, simply thickened up in these cases, and the boss piece is cast in one with a back plate, and thus bolted to the hearth back, so as to be readily renewable as in Fig. 382, 383.

The firing tools are the poker (Fig. 389), the slice (Fig. 390), and the rake (Fig. 391). A ladle is also used for lifting water from the slake trough for the damping down of the fire.

The anvil (Fig. 392) of wrought iron, steel faced, is often supported at its proper height—about 2ft.—on a block of wood, having spikes driven in at the corners to keep the anvil in

place. A much neater and better way is to have a hollow standard of cast iron (Fig. 393) furnished with ledges for the anvil, and with holes at the sides for clearing out the scale and dust. Such a casting is easily made from a pattern by coring out, gives less recoil than wood, and looks neat. Anvils weigh from a few pounds to 4 or 5 cwt., one of 2 cwt. being of suitable size for light work. The conical end is called the "beak" or "bick," the steel top the "face," the body the "core." There is a square hole, or sometimes two square holes, in the face to receive the anvil cutter and the various bottom tools.

There are such a large quantity of tools of different shapes employed by smiths that all I can hope to do is to represent some of the commoner and more typical forms, and briefly note their uses by the way. Those which are in most constant request are the hammers and tongs; after these come the different sets, swages, fullers, and flatters. A smith who works alone is vastly more limited in the number of tools which he can employ than one who has a striker to assist him. When a man is holding his work with the one hand and the hammer with the other, he cannot be holding top swages and flatters and sets as well. But when a two-handed job is required help can usually be obtained; hence I shall describe the usual tools included in a fairly complete set.

Of the hammers there are two principal types, each varying in weight and shape—the hand hammer (Fig. 394) and the sledge (Figs. 395, 396). The former weighs from 1 to 4lb., the latter from about 4 to 14lb. A hand hammer of from 2 to 3lb. weight is useful for general work, the lightest hammer, about 1½lb., being chiefly used by the smith to indicate to his striker at which points to direct his blows, the heavier hammers for drawing down and forging light works. The lighter sledges are used "up-handed"—that is, for lifting and striking in a circular arc simply, over the work; the heavier sledges are swung in a complete circle or "about sledge." The handles of each of these hammers are made of ash, well spoke-shaved, and smoothed with glasspaper, and are wedged with a single wood wedge, as shown in Fig. 397, wedges of wood being less likely to work loose than those of iron.

Taking the various tongs in order (Fig. 398), we have, A and B, the flat bit tongs, having flat parallel jaws, the width of opening of the jaws being greater in the "open mouth" A, than in the "close mouth" B; the former being used for thick, the latter for thin work, but each being similarly used for the purpose of grasping flat iron bars and sheets. The pincer tongs, C, are made in two forms, the first being simply concave in the jaws, the second vee'd as shown, the function of each being the grasping of round, square, or hexagonal bars. The hollow space behind the jaws allows of collars and similar expansions on forged work being inclosed thereby. D are tongs of similar type, but more widely useful because longer and more enlarged behind the jaws. The "crook bit tongs" E, are very common, and are made in various sizes, their peculiar shape permitting of a bar of iron passing down by the handles, while the lip on one jaw serves to retain the bar in place. The "hammer tongs" F, grasp punched work, entering into the punched holes. The "hoop tongs" G, are for holding rings of thin metal; H are "bolt tongs" for grasping bolts or rings of round bar iron; I, J, are two forms of "pliers," the latter being in constant use for general light work, picking up light rods, punches, drifts, hardening and tempering tools, &c.; K are "hollow bit tongs," made in many sizes for holding rods of circular or other section; while L and M are "flat tongs," two of the commoner modifications of the last type, and also made in several sizes for grasping flat bars of different widths and thicknesses. These embrace the principal types of tongs, but like many other tools, they rapidly increase in number, and a single forge will have from twenty to fifty pairs of different sizes and in various modifications.

All tongs are made to grasp their work by means of a "coupler," embracing the handles or reins (Fig. 398, H), and just tapped over with a hammer until they tighten themselves, so that the smith has only to turn the tongs and work about, the coupler maintaining a firm hold of the jaws on the work.

For cutting off bars, rounding edges, and rough dressing of forgings to shape, the chisels or "sets," and the gouges are employed. First there is the anvil cutter (Fig. 399), whose shank drops into the square hole in the anvil, before mentioned. The chisel edge being therefore uppermost, when a bar of cold iron is placed across it and struck with the hammer, the bar being rotated the while, the latter is nicked circularly, and may then be easily broken across the edge of the anvil, the fracture appearing of a crystalline character. The "hot" and "cold" "sets" (Figs. 400, 401) are also chisel-like tools, the difference in these consisting in the angle at which they are ground, the "hot set" being ground thin, the "cold set" relatively thick, and used as their names imply for cutting bars hot or cold. These are handled in a similar fashion to hammers, or on withy rods, or on rods of iron, the sketches indicating both forms, and the modes of handling applying indifferently to either. Tools like Figs. 402, 403 differ only in respect to their width and radii, their edges being curved to various sweeps for cutting corresponding outlines on red-hot iron. These "gouges" or "hollow sets" are struck by the sledge, the smith holding the tool by the withy handles, while the striker directs his blows on the head. The bevel is either inside or outside, and when cutting through a thick mass of iron, it is necessary to withdraw them occasionally, and dip them momentarily in water to prevent the loss of temper and softening.

Besides these there are a large number of non-cutting tools of different forms. Chief among these is the "fuller," used, as its name implies, for "fullering" or drawing down iron in a series of grooves, both for welding, or for obtaining a flat surface, or for producing a starting point from which to bend a bar. A "top fuller" is shown in Fig. 404, A, a "bottom fuller" or "anvil fuller" at B, the latter resting by its shank over the anvil hole, the former being handled hammer-like, or by withes. The top fuller may be used while the bar rests upon the anvil face, or the bar may rest upon the bottom fuller and be struck by the hammer above, or the bar may be drawn down between the top and bottom fullers, the upper one being struck by the sledge while the bar is moved into successive positions until the iron is thinned or tapered by a series of grooves. The "nicking fullers" (Fig. 404) are made in various sweeps, and they fulfil the same purpose for circular shafts and rods that the others do for flat bars.

To finish plane surfaces, the "flatter" (Fig. 405) is employed. This also is struck by the sledge, and finishes or flattens the surface, removing the uneven ridges and indentations left by the hammers and fullering tools.

The "swages" form also a very large family in themselves. They are so termed because by their agency work is "swaged" or drawn down, and made to assume definite outline corresponding with the shapes of the swages. These are, therefore, in principle dies, because the work can only assume the shapes given to the swages. Being also used in pairs, one top, one bottom, they are commonly called "top and bottom tools." Some shapes are given in Fig. 406, A, A, are bottom swages—that is, they fit by their square shanks into the hole in the anvil face; the shape of the corresponding top swages is seen at B. The ordinary shapes are the half-round, the vee'd, and the hexagonal, each being required in different sizes. Fig. 407 represents a swage block for a heavier class of work, the various sectional forms around its edges answering the purpose of bottom swages. It is conveniently laid upon a cast-iron stand, similarly to the anvil, on which stand it can also be laid flat in order that the central holes shall fulfil the functions of "heading tools"—that is, of the type of Fig. 413, for finishing the square shoulders of bolt heads, and similar flat expansions. The top and bottom swages are frequently united in one with a bent rod of iron, which serves to keep them in line, and becomes a convenient handle. They are then termed "spring swages," or "spring tools" (Fig. 408).

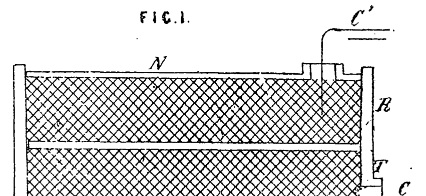
There are three modes of handling tools employed by smiths. The first, just now referred to, of wedging the hammer-head fast in the shaft. The second, that made use of with some of the sets, gouges, fullers, and flatters, in which the handle is simply thrust through an eye in the tool without any attempt at wedging, the reason being that their constant and almost close contact with red-hot iron would cause wedges to work slack almost directly. Hence the smith, previous to using either of these tools, usually strikes the butt-end of the shaft on the anvil to tighten the head. Lastly, there is the method of fixing by hazel-rods. These are straight hazel sticks of about ½in. or ⅝in. in diameter twisted round the necks of the tools (Figs. 404, 406), the elastic wood preventing painful jarring and blistering of the hand of the smith. Before being bent they are soaked in water and steamed over the fire, the operation being alternately repeated until they are sufficiently pliable to bear bending and twisting., but not taking more than a minute or two. The parallel rods are united permanently by a coupler, and are never taken off the tools except when they need renewal. Very often it is the practice to substitute iron rods for those of wood, as being more durable, the rods being bent in the same manner.

A hook wrench (Fig. 409) is used for giving a slight amount of torsion to flat bars while red hot, which have become twisted or winding in the process of forging. Fig. 410 may be taken as a type of the punches which are employed for piercing holes through red-hot iron, and Fig. 411 of the drifts for enlarging and making them parallel, the work being laid upon a bolster (Fig. 412) the while. Fig. 413 is a heading tool, of which there are several sizes used for shouldering the heads of bolts and rivets, or any work provided with collars, though where a collar is welded or otherwise formed on the centre of a bar collar swages are often used in preference.

BAILLY'S PATENT PRIMARY AND SECONDARY BATTERIES.

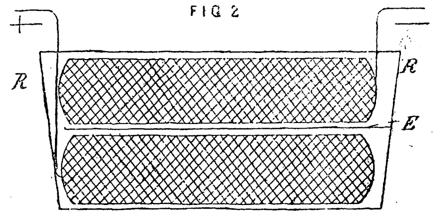
THE use of lead and zinc plates in forming batteries has latterly attracted much attention from several inventors, and amongst them M. Philimond Bailly, of Ermont, Seine-et-Oise, who has recently obtained some patents in this country for his special designs. The object of his latest published invention, so far as relates to lead electrodes or plates, is to arrange the conductors so that they permeate the whole active parts of the electrodes, and unite them without the necessity of the numerous soldered joints which are commonly used to connect the plates of secondary batteries. The lead electrodes are composed of sheets of lead divided

FIG. 1.



into filaments of suitable dimensions, which are interlaced with lead wool, and formed into cakes of any desired form or size. A mass of fine lead wool or spongy lead has been previously used; but it has been found extremely difficult to collect the currents from all parts of the mass without considerable loss, owing to the electrical resistance of the connections between

FIG 2.



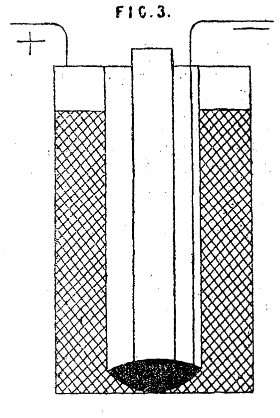
the particles of the lead wool and the conductors. With a view of keeping the resistance as low as possible, M. Bailly cuts the sheets of lead, which also act as the conductor, into coarse filaments or tapes in the manner of a fringe, which he interlaces with the smaller

filaments of the lead wool which compose the electrode. These fringes and conductors thus distribute the electricity throughout the innumerable ramifications of the filaments, and likewise also collect it during discharge, and reunite it in the common conductor. The action may be compared to the arteries and veins which permeate the human body. With this arrangement of conductor he is able to do away with the numerous joints necessary where the electrodes consist of a number of plates, also to minimise the action which takes place at the surface of the liquids, and which causes the rods or conductors to wear out or break off at the level of the liquid. That danger is in proportion to the number of electrodes, and as in his system of accumulators there is only a single conductor per electrode, the danger is reduced to a minimum.

The conductor is formed out of the same lead plate as is used for the electrode, and it can be brought out laterally or through the bottom of the jar or recipient. This arrangement is shown by Fig. 1, in which R is the jar, N the level of the exciting liquid, C[1] the conductor of the negative electrode, which, not being subject to the same danger as the positive, can be put in as usual, or, if found more convenient, can be brought out laterally. The positive conductor C, as shown, is brought out laterally by an opening, T, made tubular or otherwise, which can easily be closed with an indiarubber plug, or by cement.

Electrodes made from a mass of filaments combined with the fringes and conductors can be used for the purpose of a secondary battery in various ways. In order to obviate any chance of a short circuit they can be placed in suitable receivers, cylindrical or of any other

FIG. 3.

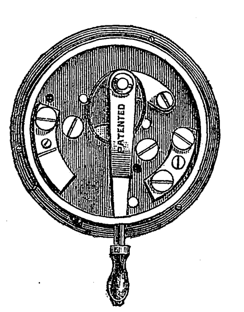


form, and separated from the electrodes of opposite polarity by some porous substance, such as felt, terracotta, or any other suitable material. The arrangement of apparatus thus made may be infinitely varied according to the requirements; thus the positive and negative element can be put indifferently either inside or outside the porous vase, or the electrodes can be put horizontally one above the other. The latter of these arrangements is shown by Fig. 2, in which R R is the receiver, — negative electrode, + positive, E porous partition of paper or other suitable material. This arrangement is especially applicable to large industrial and stationary installations, and has the advantages of cheapness and simplicity of working and construction and permanence of the active material, or the positive electrode. If desired the electrodes can be inclined so as to facilitate the easy release of the gases which are formed during the working, and the horizontal arrangement can be modified in different ways. Where it is desirable to employ an electrode of zinc, instead of using ordinary zinc, which would be attacked by the exciting fluid of the battery, the patentee makes a special amalgam of zinc and mercury, which can be run, moulded, or pressed into cylinders, plates, or any other form which it may be desirable to use. It is most important to have the zinc thoroughly amalgamated. The patentee, therefore, takes powder, filings, or fragments of zinc, and grinds and mixes them with mercury in proper proportions, in the presence of a pickling agent, if necessary, and thus forms a zinc amalgam to which any shape can be given either by casting or moulding, and pressing, and thereby squeezing out the excess of mercury. The zinc electrode can be employed in various ways: is can be placed in a vertical porous pot which is surrounded by one of the lead electrodes. The arrangement is shown by Fig. 3. In some instances holes are made in the porous partitions at the places and in the number most suitable so as to allow the issue of the liquid most saturated with the salts of the electrode, and thus prevent the increase of the resistance and the diminution of the chemical action.

If desired the zinc electrode can be placed below the lead, or it can rest above the inclined porous partition, and be either single or double or multiple, and inclined so as to allow the release of the gases, and so arranged as to have a lower part in which mercury can be placed to insure the constant amalgamation of the electrode, and receive the liquid most strongly saturated with the salts, so as not to increase the resistance on the whole surface. These arrangements can be modified in several ways. Great difficulty has been experienced in making the receivers of primary and secondary batteries water-tight: the patentee, therefore, forms them of two vessels of wood, slate, or any other suitable material, and places one inside the other in such a manner that there is a space between the two which is filled up with a material not attacked by the liquid contained in the inner vessel, and sufficiently resisting and plastic for it not to disintegrate if jarred.

THORPE'S NEW ELECTRIC-LIGHT SWITCH.

In designing this switch one of the principal features has been to put the whole of the work in the face, so that at any time a defect or alteration to wires can easily be effected.



The spring has a direct action on the lever, or has no tendency to pull it over on one side, as is the case with many now in the market, and the action is very quick in either direction. The switches are all arranged to take a fusible wire, and they can be made with either wood or porcelain covers, and owing to the simplicity of construction they can be made at a low price.

SIMPLE EXERCISES IN TECHNICAL ANALYSIS.—XIX.

By an Analytical Chemist.

Colza Oil.

(249.) *Sp. Grav.*—The percentages obtained at the following gravities are:—

·9135 to ·9139	....	6 per cent.
·914	....	37 „ „
·915	....	25 „ „
·916	....	12 „ „
·917	....	18 „ „
Above ·917	....	2 „ „

A gravity of ·917 is too high, and the samples of that density, although amounting to 18 per cent. of the total number, were an exceptional lot. Most of them were submitted at the same time by the same merchant, and they were found to be genuine, but of abnormal gravity. The table shows that the greater part of the oils lies between ·914 and ·915; well refined oils may fall as low as ·9135 (the lowest figures obtained), and cruder oils may rise as high as ·916.

(250.) *Rise of Temperature with Sulphuric.*—The figures obtained by the following specialists are:—

Allen	91° to 108° F
Maumené	104°
Archbutt	106°
Baynes	108° to 165°.

The latter are probably too high; my own experience, or, so far as I know, that of any other analyst, does not confirm them. Three samples specially obtained and kept as standards gave three sets of figures: the first (described as "Best refined oil") gave a rise of 85° Fahr. and a gravity of ·9137; the second, which had been practically tested for illumination on a large scale and had given complete satisfaction, gave a rise of 96° Fahr. and a gravity of ·9147; while a third gave a rise of 102° Fahr. The results obtained from commercial samples vary considerably; but general experience tends towards fixing a temperature about 100° Fahr. as the standard for genuine colza oils.

(251.) *Cooling.*—Fat begins to deposit at about 24° to 21° Fahr.

(252.) *Drying Properties.*—Oxidises when exposed; but cannot be said to dry at ordinary temperatures.

The elaïdin test gives in about 20 hours a solid of the consistence of butter, and of an orange colour.

(253.) In oil required for burning in lamps the percentage of free acid should be low. (See Art. 230, *d*).

(254.) A drop of sulphuric acid let fall on twenty drops of the oil, as described in Art. 230 *e*, gives a characteristic colour. A yellowish brown spot forms the centre of a gradually extending purplish slate-coloured circle.

(255.) The viscosity test is of particular importance. Glycerine of sp. gr. 1·226 and genuine rape oil have the same viscosity; glycerine serves, therefore, as a useful standard in the absence of a sample of guaranteed purity.

(256.) Colza oil is so little soluble in acetic acid that this is a valuable distinctive test.

(257.) Colza is usually of a light yellow colour, and when well refined almost odourless. Rape oil has a brownish colour, and a characteristic odour; in other respects it so closely resembles colza that they may be regarded as practically identical.

(258.) When colza oil is specially examined to determine its value as an illuminant, a measured quantity of oil is burnt in a particular lamp. When all the oil is burnt the lamp goes out, or it may go out before if the oil is of bad quality. The time the lamp continued lighting is noted; also the condition of the wick after the experiment. An equal measure of a standard oil is burnt in the same lamp under precisely similar conditions, especially as to length and thickness of wick. Good oils burn longer and char the wick less. This is a useful practical test.

Castor-Oil.

(259.) *Sp. Gr.*—·962 to ·963.

(260.) *Rise of Temp.*—Maumené and Archbutt give 84° to 82° Fahr., Allen as high as 117° Fahr. My own results agree with those of Maumené.

(261.) Castor-oil usually becomes cloudy in the ice-chest, although when cooled to 14° Fahr. it does not deposit fat. At this latter temperature it is very thick. It solidifies at 0° Fahr.

(262.) *The Elaidin Test* yields a semi-solid mass of a greenish or more usually a yellow tinge.

(263.) *Colour Test.*—With a drop of sulphuric to 20 of oil, a yellowish orange spot is produced.

(264.) *Solubility in Alcohol, &c.*—Readily soluble in hot or cold alcohol (65 o.p.).

It is also very soluble in glacial acetic acid, but insoluble in petroleum spirit. The latter is a good distinctive test.

(265.) "Cold-drawn" oil is colourless, or straw yellow; lower qualities are darker coloured, with a tendency to darken more and to become rancid. The taste and odour of castor oil are particularly disagreeable to some persons.

Ordinary adulterants may be detected by the above tests.

The viscosity of this oil is greater than that of any other fixed oil.

Niger-Seed Oil.

Not often met with commercially.

(266.) Sp. gr. ·926.

(267.) The rise of temperature with sulphuric was only 119° F., which is considerably below that usually stated.

(268.) *Colour Test.*—One drop of sulphuric to 20 of oil produced a yellow spot, turning to dark red, then dirty brown, with a violet tinge.

Cocoanut Oil.

(269.) The sp. gr. at 100° F. is almost uniformly ·910 to ·911.
(270.) The melting point is 70° to 71° F.
(271.) *Free Acid.*—Frequently considerable.
(272.) It is of the consistence of butter, of a white colour, and peculiar odour and taste. It is much used for marine soaps.

Cottonseed Oil (Refined).

(273.) Sp. gr. ·922.
(274.) *Colour Test.*—With sulphuric acid the colour produced is nearly the same as that from olive oil; it can, however, be distinguished from the latter by other tests.
(275.) The reactions for this oil are only of importance in detecting its use in the adulteration of olive and other high-priced oils. A recent decision given in Glasgow against two grocers puts this question on a higher level. This decision declares olive oil to be an article of food, and the addition to it of cottonseed oil an offence under the Foods and Drugs Act.

(*To be continued.*)

PHOTOGRAPHIC LENSES.*

By J. TRAILL TAYLOR.

WHILE there are few lenses which cannot, in some way or other, be made to conduce to the formation of a photographic image, yet does the photographic objective differ *per se* from all others in certain characteristics. Arriving at a definition of what forms a photographic lens by contrasting it with the object-glass of a telescope, we find that, whereas the function of the latter is to produce an image of objects which are transmitted axially, or in near approximation to the axis, the former must not only do this, but more, for it has to take account of rays transmitted also at considerable obliquity to the axis, and, after such transmission, has to project these oblique rays to distances proportionately greater than axial ones ere they come to a focus, in order to supply the condition of a flat field. Hence the greater the obliquity of the pencils, the more elongated must be the converging beam, in order that this indispensable condition be fulfilled.

It not unfrequently happens that in a photographic lens corrected perfectly to work to focus in the centre of the field the photographic definition towards the margin will be found to be of a higher class than the visual image. From this we may deduce the fact that a formula by which direct or axial rays are achromatised does not include the case of oblique rays otherwise than as an approximation.

It was reserved for the genius of Professor Petzval, of Vienna, to make the grand discovery of the portrait lens. A year after Daguerre's discovery, the late Voigtlander, when calling upon Professor von Ettingshausen, was asked by that gentleman whether he could determine the refracting and dispersing power of different descriptions of crown and flint glass, because Professor Petzval who was at that time filling the mathematical chair in the University at Vienna, had made the calculation of a photographic lens which could not be executed in consequence of the qualities of the glass to be employed not being then in existence. Voigtlander, intimating his ability to do this, was asked to call immediately on Petzval, and the portrait lens was issued about 1841. Of all lenses extant, it is the one possessing the greatest angular aperture, by which term is understood the diameter of the lens in relation to its focus. In former times, when processes were less rapid than they now are, it is easy to conceive of the impetus given to portrait photography by the discovery of Petzval.

If a plano-convex lens, or one nearly of this form, be inserted in a camera and directed to the light, it will be observed that if the convex side be turned towards the view, an image more or less sharp will be formed at the focus, but that the area of sharpness will be exceedingly limited. By reversing the position of the lens, turning the flatter side out, the opposite result is obtained—there is no sharpness anywhere, but a generally better and more uniform image all over the focussing screen. This arises from spherical aberration, the margin of the lens when thus placed bringing the rays to a focus anterior to that effected by the central portions.

The condition for reducing this confused definition to sharpness is that a diaphragm shall be inserted in front of the lens under such circumstances that the centre of the picture shall be formed only by the centre of the lens, no rays finding admission to the margin of the lens but those which come from the side of the view to be delineated, and thus fall upon the surface in a more or less oblique manner. This diaphragm is therefore absolutely necessary with a lens of the nature described, in order to secure flatness of field, with good marginal as well as central definition. It is, therefore, necessary that the diaphragm be situated a little distance in front of the lens, because it is only when thus placed that rays are allowed access to to the lens, subject to the conditions mentioned, those which would mar the sharpness being thus excluded. It must not, however, be imagined that the same effect would be produced by reducing the diameter to the size of the aperture in the diaphragm, for in such a case, while the centre would be sharp as before, the sides would be badly defined.

What has been said of the plano-convex lens is also true of the meniscus. This latter lends itself, by its form, so well to the transmission of rays possessing a great degree of obliquity to the axis, that all lenses which are intended to embrace a wide angle of subject must be of this form; but the spherical aberration being greater in a deep meniscus than in a flat lens, a stop somewhat smaller is requisite, in order to its reduction.

Aplanatism is a somewhat ideal term, and cannot with strict accuracy be applied to photographic lenses. It was originally employed in 1791 by a Scotch *savant*, Dr. Bird, to denote lenses free from spherical aberration, in like manner as achromatism signifies freedom from chromatic aberration. Popularly it is held to designate an objective which gives sharp central definition with its full aperture, no diaphragm being employed. But this even an imperfectly corrected lens will do, provided its diameter be sufficiently reduced. We can, therefore, only talk in this connection by degrees of aplanatism, which would be the better understood if we had a zero from which to start the scale. This zero might be made to equal $\frac{f}{1}$, or a diameter equalling the focus; but at any rate, the term as it at present exists has not a sufficiently definite meaning. With this by way of protest against the mythical expression, I observe that of all photographic lenses extant, the old portrait combination is that in which the property of aplanatism, or maximum angular aperture, is greatest. As is the relation of aperture to focus, so is the intensity of the illumination. While a large angular aperture conduces to rapidity, in the same degree is it adverse to penetration, or the property of presenting on a plane surface, and with a degree of definition which satisfies the requirements of the artist, objects situated at various distances. This property of penetration, or depth of defining—unthinkingly called "depth of focus"—is a power of great value to the photographer, and is induced by means hereinafter described.

The Optical and Focal Centre.

It is in many instances desirable that one should be able to know where the optical centre of a lens is situated. It is a property of this centre that any ray refracted by the lens which passes through it emerges in a direction parallel to its incidence. It is from a point near to, although not quite at, the optical centre of a lens, or combination of lenses, that the focus must be measured. To find this centre draw two parallel radial lines, one from the centre of each curvature, and both being oblique to the axis; then connect the points at which they touch the curved surface by a line, which, in the case of a meniscus, must be prolonged till it meet the axis. The point at which this junction-line touches the axis is the optical centre. In class books on optics the following rule is given: "Multiply the thickness of the lens by the radius of one surface, and divide the product by the sum of the radii, and the quotient is the distance of the centre from the vertex of that surface."

In a *combination* of lenses there is no fixed point which can be termed the optical centre. The mistake is frequently made of assigning it to a position near the diaphragm which has not necessarily any relation to that of the centre, which can only have its position determined upon knowing the precise circumstances under which the combination is to be used, for it has strict relation to the conjugate foci. What is commonly termed the optical centre in a combination is in reality the centre of conjugate foci, and this is determined by the conjugates, which may change with nearly every change of picture taken.

The *equivalent focus* of a lens is so termed from an image formed by it equalling in dimensions that made by a single lens. It has no relation to the misleading term "back-focus," so frequently employed. It is not difficult to conceive of an objective, the back-focus of which—that is, the distance between the posterior surface and the ground glass of the camera—may be 4in., while the real or equivalent focus is 8in. As it is of great importance that photographers know precisely the foci of their lenses, I shall describe methods by which this may be ascertained. Let me first of all observe that, although it has been taught by some that the focus must be measured from the optical centre, this is not quite correct. In every lens or combination there are two nodal points, which are centres of admission and emission. They are sometimes designated the Gauss points, from the fact of Gauss having communicated an investigation of their properties to the Royal Society of Göttingen in 1840. In the case of a simple bi-convex lens these points are situated between the optical centre and the surface, while in a meniscus lens it is outside of the lens, and a little within the optical centre. It is the back nodal point which concerns us at present, as that is the one from which the focus is measured. In a rectilinear combination this posterior focal centre is situated between the diaphragm and the back lens. Opticians interested in this are referred to Secretan's treatise on the true point from which the focus should be measured, or to Gauss's memoir.

It has often been recommended to determine the true focus of a lens of this nature by focussing the camera upon an object, so that the image and the object shall be of precisely the same size, and divide the distance apart of the two by four, the quotient expressing the true equivalent focus of the lens. This is altogether misleading as applied to the combination lens in common use, the focus thus obtained being greater than the true focus by nearly one-fourth of the distance at which the lenses are separated in the mount.

Out of several methods by which the equivalent focus may be ascertained, I shall mention only a few. Select a very thin spectacle glass which, after trial is found to give an image on the focussing-screen of the same dimensions as that given by the photographic objective; and the distance of that glass from the focussing-screen, less one-fourth its thickness, is the focus. Or, having marked upon the ground-glass the precise spots upon which two well-defined objects depict their images near the margin on opposite sides of the screen, unscrew the lenses from the mount, and insert a pinhole diaphragm made in a thin metal plate. Rack the camera in or out until the images made by the pinhole correspond with that of the lens in dimensions. As before, the distance between the ground-glass and diaphragm is the focus.

The way which I prefer is Grubb's, on account of the ease with which it may be carried into operation and the accuracy of the result. On the ground-glass of the camera make two pencil marks at either end, each being a distance of an inch or so from the margin, although this is not material provided both are alike as regards distance. Having brought up a table to the window, spread upon it a sheet of paper, and upon this place the camera. Focus upon a distant scene, and rotate camera until a well-marked object in the scene—such as a chimney or spire—is superposed on one of the lines drawn on the ground-glass. Now using the side of the camera as a ruler, draw a pencil line upon the sheet of paper upon which the camera is placed, and rotate the camera so as to superpose the same object upon the other mark on the ground-glass, and again draw a line upon the paper. Having removed the camera, for which there is no more use, continue by aid of a flat rule these two angular lines until they meet at a point, then connect them by a line as in the capital letter A, which line must equal in length the distance between the two marks made on the ground-glass, and with a foot-rule measure the junction of the angular lines to the centre of the cross line, and you have the true focus of the lens.

Schroeder's method is also simple and excellent, although it implies the possession of a camera capable of extending to about twice the focus of the lens. Extend the camera until the dimensions of the image on the ground-glass and of the object in front are alike. Having marked the position of the camera back in relation to its baseboard, slide or rack it in until a distant object is in focus, and again mark the position of the back. The distance between the two positions, or that through which the camera-back was made to travel from the first focussing to the second, gives the equivalent focus to the lens. In a rectilinear symmetrical doublet of wide-angular aperture which I possess, having an equivalent focus of 13¼in., a reputed focus of 13in., and a back focus of 10⅝in., I find that the focal point or posterior nodal, is situated ·3in. back of the mechanical centre of the lens. This is a matter that greatly concerns those who have to make copies to scale, and who have the sides of their cameras graduated in order to facilitate accuracy and speed.

The earliest form of objective was the plano-convex, or slightly curved meniscus. For reasons already given, it has a diaphragm, or stop, in front. In order that it should work with a larger aperture, the late Mr. Grubb reversed the relative positions of flint and crown, by which he was enabled to bring the diaphragm rather closer to the lens. Still later, the late Mr. Dallmeyer modified it by placing the flint between two crowns, for which further advantages

* Abstract of a paper read before the Society of Arts.

were claimed. By recent improvements in the selection of glass, and curvature, this old objective (which in all its various forms is still much employed) is now made with such a large fixed diaphragm, as to render it capable of being employed in portraiture. This, of course, is owing to the minimising of the spherical aberration. Whilst admirable in other respects, it is unsuitable for copying or for architectural purposes on account of its refracting the lateral rays in a greater proportion than the central ones. This distortion does not show near the middle of a picture, but becomes apparent when the included angle is moderately wide. From the nature of its construction it cannot supply the condition of orthographic projection—viz., that a ray shall emerge in a direction parallel to that at which it enters. To this end the ray would have to pass through the optical centre, which in such a lens cannot be done.

The Petzval portrait lens consists of a nearly plano-convex achromatised lens in front, with a double convex posterior lens at the other end of the tube. This latter is composed of a bi-convex crown and a concavo-convex of flint glass, the inner curves not being concentric, and the two are separated to a slight extent. This back combination fulfils a two-fold function: it shortens the focus and thus intensifies the illumination, and as it possesses a large degree of negative spherical aberration, it counteracts the positive aberration of the front lens, and thus with a large aperture it brings rays to a sharp focus over a field quite large enough for single portraits. Some years ago, Dallmeyer introduced a modification of the back lens, reversing the relative position of its element, as Grubb had done with the landscape lens, the requisite negative aberrations being obtained, as in the Petzval back, by the inner surfaces not being concentric. This form of back lens lends itself to the lowering of definition, when such is desired, as in the case of large faces in which the rugosities of the skin are not always desirable.

An American optician, Morrison, makes some of his portrait lenses—especially those for taking a large standing figure with full aperture—with an uncemented front lens and a Petzval back, the inner surfaces of the front lens having non-concentric lenses.

The most recently introduced lens of the portrait class owes its inception to Steinheil, and is constructed on lines quite different from all others. The front is a cemented positive combination, and consists of a convex crown and a concave flint. The back combination is composed of a bi-concave flint and a bi-convex crown, these being separated to some considerable extent. Each combination exhibits chromatic and spherical aberration to a large extent, but in an opposite sense, so that the two combinations correct each other.

(*To be concluded.*)

STANDARD SCREW THREADS.*

By JOSHUA ROSE.

THE angle of the sides, one to the other, of the United States Standard, of the common V, and of the steam and gas thread, is said to be that of 60°; but it can be shown that a thread can only have a standard angle upon one diameter of bolt or work, and that for this one diameter the angle of the thread is different from that of the tool that cuts it. This in no way detracts from the value of a standard, because it is by means of the standard that we are enabled to originate threads,

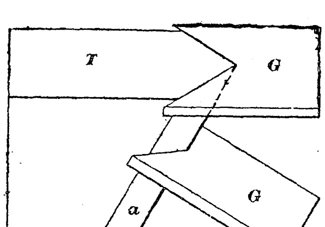


Fig. 1

and be sure that all those of a given pitch will fit, let the diameter of the work be what it may, and the actual angles of the threads vary as they may, upon different diameters of work.

Let it be supposed that a thread is to be originated, its sides to have an angle of 60°, and there at once arises the complicated problem as to what shape the cutting tool must be to produce threads having that angle, for the angle of the tool differs from the thread it produces. This fact may be stated in another way, inasmuch as that the angle of the cutting edges of a tool differs from the

* From the *American Machinist.*

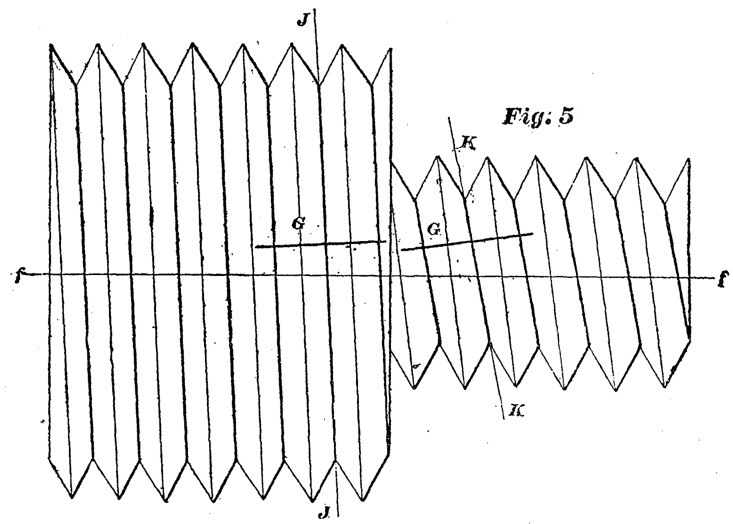

Fig. 5

Fig. 3

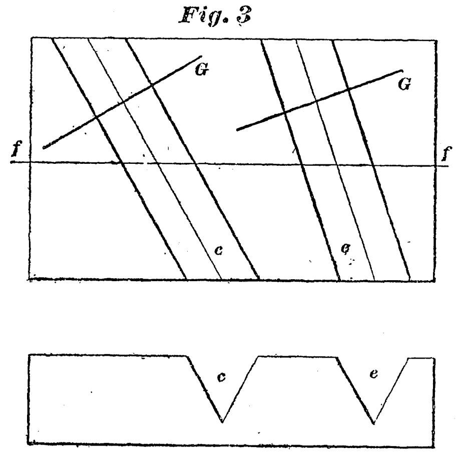

Fig. 4

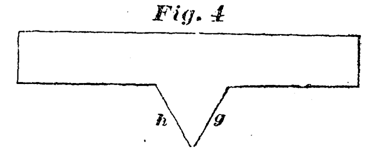

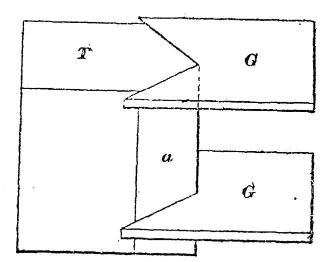

Fig. 2

angles of the two clearance faces, which are factors in producing the cutting edge. This is shown in Fig. 1, where T is a tool, and G a gauge of an angle of 60°. By grinding the end faces *a* of the tool at such an angle that the gauge fits the cutting edges of the tool, the cutting edges will obviously have an angle of 60°, measured on the plane of the top face of the tool; but if we apply the gauge to the clearance faces, as *a*, we must hold it at a right angle to those faces, as at G', and it will then no longer fit, and it is clear that the production of cutting edges at an angle of 60° can, in a tool of this kind, only be obtained by grinding the end faces *a* (these being the only ones that are ground in resharpening the tool) to some other angle, and and that this latter angle depends upon the amount of clearance given to the tool may be shown as follows:—Suppose the tool is given no clearance, as in Fig. 2, and the gauge may be applied parallel to the top face of the tool, and at any part of the tool depth, and will still show the same result; or, in other words, if it fits the tool in position G, it will also do so in G'. But the tool must have a certain amount of clearance on its end faces *a*, in order to enable it to cut, and it follows that for every variation in the amount of clearance the end faces *a* must be ground to some angle other than that of 60° in order to produce cutting edges that shall be at an angle of 60°.

In the practice of the ordinary workshop this has a minor importance, because, so long as the tool is ground so that it fits the gauge when applied in position G in the figures, the workman need not concern himself with what particular angle or amount of clearance he has given to the tool in order to obtain correct cutting edges, all that he needs to insure being that the cutting edges are at the correct angle, and that the amount of clearance is suitable for the diameter of the work the tool is to operate upon, and the pitch of the thread the tool is to cut. But in the manufacture of threading tools it assumes great importance, because the fit-and-try process is too expensive; hence a definite degree of clearance is adopted, and with it such an angle of end face as will produce cutting edges of the correct angle, when the gauge is applied parallel to the upper face of the tool.

When we come to apply a thread gauge to the work we are met with new considerations arising from the angle of the thread to the axis of the work, every varying angle giving in reality a different form of thread, although all the threads may be cut by the same tool, and furthermore, although all the threads may appear correct when tested by a gauge applied parallel to the axis of the work.

But the actual angle of the threads cannot be measured in this way, as may be seen in Fig. 3, in which a rectangular piece of work is represented as having two V grooves, *c* and *e*, cut in it at a different angle to the line *f f*, which may be taken to represent the axis of the work.

Suppose it was required to produce by hand a number of such pieces of work in which the grooves were to be exactly alike, and a male gauge such as in Fig. 4 must be made to test the grooves, the sides *g h* being at an angle of 60° one to the other.

In applying this gauge to the work it must obviously be held at a right angle to the length of the grooves, as at G for groove for *e*, and at G' for groove *c*, and when so applied the grooves fitted to it will have their sides at an angle of 60°, let their angle to the line *f f* be what it may.

But if we then apply the gauge on the line F F, neither of the grooves would appear to be correct, nor would any groove, unless the centre line of its length were at a right angle to the line *f f*.

That a screw thread must, in order that its sides be at an angle of 60°, be measured in the same way is obvious, from Fig. 5, which represents two screw threads having the same pitch, but upon different diameters of work. Line *f' f'* is the axial line of the work, and corresponds to line *f f* in Fig. 3. Line J J is the centre line of a thread groove, G represents the gauge applied, as at G in Fig. 3, at a right angle to J J, and G' the gauge applied at a right angle to centre line K K of thread groove, hence if the sides of both grooves were at equal angle the gauge would fit equally to both. But in cutting the thread, the plane of the cutting edges is parallel to the axis *f f*, and in gauging it the gauge is also applied parallel to the axis; hence the angle of the thread varies upon every different diameter of the work, and can only be a standard angle when a certain thread pitch is considered with relation to a definite diameter of work, as in the case of the United States standard.

But so long as the tool and the gauge are both applied parallel to the axis, work threads of equal diameter and pitch will fit together correctly, notwithstanding that the thread angles may vary with the work diameter. Hence, it is to be considered which is the most convenient method of cutting and of gauging the thread.

THE Manhattan Elevated Railway Co. is adopting solid brass driving boxes for its locomotives.

STEAM-PROPELLED TORPEDOES.

THERE is at the present time undergoing consideration by the Admiralty authorities a system of propelling travelling torpedoes by means of steam instead of by compressed air, devised by Mr. Edward C. Peck, who is engaged in the constructive department of Messrs. Yarrow and Co.'s torpedo boat-yard at Poplar. The torpedo is of the usual Admiralty pattern outside, the dimensions being 14ft. long by 14in. diameter, and it will carry in the forward part an explosive charge of 100lb. of guncotton together with the firing apparatus. The shell will be constructed of metal, and will be sufficiently strong to resist the external pressure of the water and atmosphere when a vacuum is formed within it. At about the centre is a hot-water reservoir 4ft. long and 11½in. internal diameter, and capable of withstanding a given pressure. This reservoir will be surrounded by a coating of non-conducting material ⅝in. thick, and between the outside of this and the skin of the torpedo will be a space of ⅜in. The reservoir is to be charged with about 160lb. of hot water taken from the main boiler of the torpedo boat or other vessel from which the weapon is to be discharged. The water will be transferred very rapidly at a pressure of about 400lb. per square inch by means of a tube fitted with the necessary inlet and outlet valves, and there will be means for raising the temperature of the water, if necessary, during its transfer from the boiler of the boat to the reservoir of the torpedo. The charging operation will not occupy more than half a minute, and it is calculated that the torpedo will keep steam at the pressure necessary for driving her engines for at least an hour after it has been charged. The quantity of water carried will possess sufficient sensible heat to supply the propelling engines with steam of a slowly decreasing pressure during the run of the torpedo. The space between the reservoir and the skin of the torpedo, as also a portion of the space in the body of the torpedo not otherwise occupied, is utilised as a surface condenser for the steam after it has done its work in the engines. By this means the weight of the torpedo will be precisely the same at the close as at the commencement of the run. The torpedo will be fitted with engines of 60 H.P. indicated, and capable of propelling it through the water at a speed of 32 knots an hour. It will be fitted with the usual fins, rudders, and regulating apparatus to insure its travelling at any required depth and in any desired direction. The advantages of a steam-driven torpedo would appear to be very considerable. In the first place weight is saved in the torpedo itself, and, the pressure being only about one-fourth of that in the Whitehead torpedo using compressed air, there will be no difficulty in keeping all the joints and connections tight. In the next place, compressed air will only give a three-quarter minute run, while it is calculated that steam will give a run of a minute and three-quarters. The speed with compressed air is 24 knots, and the average range 600 yards, while with steam Mr. Peck reckons on a speed of 32 knots and a range of 1,800 yards.

A NEW MICROSCOPE.*

I HAVE much pleasure in bringing before you to-night a new microscope made by Mr. C. Baker, which I think you will all admit begins a new era in the progress of "microscopy." You have before you for the first time in the history of the microscope a thoroughly sound full-sized instrument at the same price as a student's microscope. I must say that we are all greatly indebted for the construction of this instrument to the energy and perseverance of Mr. Charles Lees Curties. I will, if you will allow me, just go over some of the points adopted in this new microscope. I say adopted, for in a new microscope there must of necessity be much that is old in design, &c. All that can be expected is that some of the points are to be new. This therefore will be found to be an aggregation of late improvements with some new excrescences added. Let us begin with the foot (a most important part.) All microscope feet may be classified under four heads:—1st. The simple tripod, illustrated by the Powell form. 2nd. The plate and uprights. A flat plate with pillar or pillars, as in the Beck model, and a plate with flat uprights in the Andw. Ross. 3rd. The bent claw, a very common and bad form, used by many makers. 4th. The heavy horseshoe, the usual Continental model. The plate and uprights is a good form, but was not adopted because it is too heavy and expensive. The bent claw is a bad form. It is surprising that it has not disappeared long ago. It is heavy, easily capsized, and while seemingly a tripod, often rocks on four points. The heavy horseshoe which, until lately, was always fitted to students' microscopes, has nothing to recommend it. A designer must indeed be hard up for resources who can only obtain steadiness by weight. There can be no question but that the tripod in its simplest form is the best. Of all the ways of utilising it, that adopted by Messrs. Powell and Lealand is the most efficient—viz., of hanging the microscope in a horseshoe, supported by three legs; but that for this class of instrument was quite out of the question, for cost immediately puts it outside the category of students' microscopes. There is a great difference between the steadiness of a microscope perched up on the top of its trunnions, and one that is hung in a tripod. This microscope is placed in a kind of stirrup hanging from the trunnions, a most ingenious device of Mr. Curties. The body is large enough to take Zeiss full-sized eyepiece—viz., 1⅜in., and is 10in. long when the draw-tube is pulled out to a mark. When the draw-tube is pushed home the length is 6·3in., or Continental gauge. It, therefore, will suit both kinds of apochromatics. The optic axis of the instrument, when in a horizontal position, is 8½in. from the table. It has rackwork, coarse adjustment, and Campbell's fine adjustment. It is to this fine adjustment that the instrument owes its origin. The moment Mr. Campbell explained to me the principle of his fine adjustment, I foresaw the construction of an efficient student's microscope. The direct-acting screw is only suitable for low powers and small apertures. I will put it even stronger: delicate work with high powers and wide apertures is not possible with any microscope having a direct-acting screw fine adjustment. The stage is of the cut horseshoe form, which I had the honour of bringing before you some little time back. The principal object of it is to enable you to feel your working distance. Let me point out a great improvement in the sliding bar. Its guiding lugs are stowed away underneath the stage; I have no hesitation in saying that next to a perfect mechanical stage this is the best. Most of the mechanical stages are so defective in design, and so scamped in their workmanship, as to be worse than useless. The substage is fitted with a tube, having a spiral slot for focussing, which I will pass over, having described it here on a former occasion. There is a novel feature about the stops for dark ground illumination—viz., there is a three-legged carrier which holds them all. This carrier has a pin in the centre of it on which the various sized discs fit. The stops, diaphragms, &c., have a separate tube-fitting for them, so that it is unnecessary to move your condenser when changing either a stop or a diaphragm. This substage will carry either of Prof. Abbé's condensers, or a cheap condenser made especially for this microscope. The weight of the microscope is 7lb. complete. **Edward M. Nelson.**

* Read before the Quekett Microscopical Club, Jan. 28th, 1887.

Nickel Crucibles.—Pure nickel is one of the toughest of metals, it fuses only at very high temperatures, and has a fine grain susceptible of of high polish. These qualities have led to its being used for chemical crucibles and evaporating dishes. For many purposes they are quite as serviceable as platinum ones; and cost only one-tenth the price of platinum. They stand alkalis well, Mr. Wanklyn having found that there was no alteration of weight in the crucible after caustic potash was fused in it. Hydrochloric acid, dilute or concentrated, may be used in the cold to clean them, so also cold vitriol, but concentrated nitric acid attacks them. They can be used for taking water residues.

Locomotive Crank-Axles.—The failure of crank-axles is one of the most important questions that requires the attention of locomotive engineers, and some particulars of breakages on the Northern Railway of France, which are quoted in the current volume of the *Proceedings* of the Institution of Civil Engineers, will be read with interest. The details are taken from the *Annales des Mines*, vol. ix. page 335. The period embraced extends over the five years between 1881 and 1885, during which time there were 58 cases of breakages; one in the bearings, five through the webs, and fifty-two through crank-pins. During the same period 100 axles were condemned. These figures show the crank-pin to be in general the weak spot, and this is of course in accordance with ordinary experience. It is suggested that by drilling an axial hole 2⅜in. in diameter through each crank-pin it would be weakened to a very slight extent, while the insertion of a bolt would add enormously to its safety. Such a bolt would be subject only to sheering strain, and its full area would therefore be efficient. This plan would necessitate no extra room, which is an important point, for though the crank-pins might be increased in diameter the practice would be inconvenient on account of the additional size of big ends that would be required, and the consequent raising of the boiler. It is said that the cost of drilling and bolting two crank-pins would be £1 12s. The cost of shrinking four hoops on to the crank webs to strengthen those parts is set down at £5.—*Engineering.*

SCIENTIFIC NEWS.

THREE new comets were discovered in the last half of January. The great comet announced by telegram from Melbourne was, it appears, discovered by Dr. J. M. Thome, of Cordoba, on January 18th, and was duly circulated by Prof. Krueger from Kiel. According to the Dun Echt Circular, No. 133, Prof. Krueger subsequently telegraphed that the head of the great comet had been observed at Melbourne on Jan. 23, Melbourne M.T. 8h., in R.A. 21h. 20m. 28s.; S. Dec. 44° 17′; daily motion plus 10m. 24s.; 51′ south. In physical appearance it resembles the great Southern comet of 1880, and is expected to become very brilliant. A telegram from Melbourne dated Jan. 31 says that the comet has ceased to be visible there. Dun Echt Circular, No. 132, announces the discovery of a faint comet by Mr. W. R. Brooks, of the Red House Observatory, Phelps, New York, on Jan. 22, at 6h. 54m. local time. It was observed at Strasburg on Jan. 25, the position at 8 p.m. (local time presumably), being R.A. 18h. 29m. 15s.; N. Dec. 74° 19′. It was faint, and moving slowly in an easterly direction. The third comet was discovered by Mr. E. E. Barnard, of Nashville, Tennessee, on Jan. 24, and the following position is given from an observation at Harvard College, Cambridge M.T., Jan. 24, 17h. 55·7m., R.A. 19h. 10m. 17·4s.; N. Dec. 25° 57′ 45″. Daily motion plus 2m. 36s., 75′ north. This comet is also described as faint.

The *Annuaire de L'Observatoire Royal de Bruxelles* for 1887 contains, besides a variety of information of more or less interest, M. Lancaster's useful general list of observatories and astronomers.

The death is announced of Mr. Hilborne L. Roosevelt, the most famous of the organ builders of America, at the early age of thirty-six. We described the large instrument he built for the cathedral in Garden City, Long Island, in Vol. XXX. p. 525, and Walcker's electro-pneumatic movement in No. 1130.

The deaths are also announced of M. Feil, the well-known maker of optical glass; of Prof. Trasenster, Liège University; of M. Mercadier, professor of physics in the Paris Polytechnic; and of M. Fontannes, the French geologist.

It is proposed to hold the first meeting of the Australasian Association for the Advancement of Science in 1888, the hundredth anniversary of the colonies of Australia and New Zealand. The rules are based on those of the British Association, and the aims and objects of the new society will be much the same as those of the old.

At a recent meeting of the Linnean Society, Prof. Bayley Balfour exhibited specimens and microscope slides of the "gingerbeer plant," and pointed out that although well known to many as an agent in the manufacture of an acid drink from sugar, water, and ginger, very little had been published in connection with its life-history. It has the appearance of a white Nostoc, and is composed of a bacterium (passing through all forms of rods, coils, and filaments) which apparently constitute its greater part, and associated with this is a sprouting fungus. Judging from descriptions and figures by Kern of the "kephir" used in the Caucasus to induce fermentation in milk, the gingerbeer plant closely resembles that, though there are many points of difference. It is said that its introduction into Britain was by soldiers from the Crimea. Prof. Balfour will be glad to have specimens of the plant from different localities, and any notes which serve to throw light on its life-history.

A new food for cattle has been patented in Germany, which shows to what lengths food reform may ultimately extend. It is stated to consist of wood sawdust mixed with certain chemicals and "other matter," the composition forming a "very nourishing and wholesome" food for pigs, cattle, and horses.

A consignment consisting of one million and a half of whitefish ova (*Coregonus albus*) was received by the National Fish Culture Association the other day from the American Government, and laid down in the hatchery at Delaford Park. The United States Fish Commissioners

desire especially the introduction of this valuable Transatlantic food fish to the waters of the United Kingdom, especially Scotland, whose lakes are best adapted to its natural necessities. The aquarium erected by the executive of the Fisheries Exhibition at South Kensington was sold at auction for about £100. It was hoped that it would be maintained as part of the Buckland Museum, especially as it was the only one in London worthy of note.

In his inaugural address as president of the Manchester Association of Engineers, Alderman W. H. Bailey spoke of the chief mechanical inventors of Lancashire, and gave an interesting epitome of what they had done. At the time of delivering the address Sir Joseph Whitworth was still alive; but Alderman Bailey said he intended to treat upon Whitworth's contribution to the utility of mechanical tools and to workshop law at another time.

An improved method of producing sodium has been devised and carried out in practice by Mr. Castner, of Belvedere-road, Lambeth, and a full account will be given in a paper to be read before the Society of Chemical Industry on March 7. A compound is prepared by coking iron and pitch together, and that is used as the reducing agent in large steel crucibles. It is stated that from a quantity of caustic soda, which will cost fourpence, a pound of sodium can be obtained at an expense of a shilling when the process is worked on the large scale.

Cheap sodium means cheaper aluminium, but we shall probably obtain that from the Cowles' electric process, as we learn that works are to be erected in this country shortly, and Messrs. Crompton have already been instructed to build a dynamo fifty per cent. larger than the "Colossus" made by the Brush Co., and now running at Lockport, New York. Two other dynamos, each of which is to have a minimum working capacity of more than half a million watts are being contracted for. They will each require over 800H.P., and altogether the plant will involve the erection of engines capable of yielding 3,000H.P.

At a recent meeting of the Physical Society, Mr. C. V. Boys directed attention to some excellent photographs of the solar spectrum just received from Johns Hopkins University. They had been obtained with the assistance of Prof. Rowland's gratings.

It is stated that Messrs. Siemens and Halske, of Berlin, have introduced a compact and portable apparatus, consisting of a "metre bridge," in which the wire is bent into a circle and the galvanometer is replaced by a telephone.

Mr. Magnus Maclean, M.A., the official assistant to the professor of natural philosophy in Glasgow university, has issued (James Maclehose and Sons) "Examples of Exercises," given in the class from 1865-1885, with "indications how to answer them." The little book will be welcomed by all students, more especially by those who are unable to appeal to a teacher for assistance in thinking out a problem. It will be understood that answers are not supplied to all the questions; but "indications" are afforded which will help the really earnest student to do his work well.

It is stated that the specimens of clay from the Royal Society's borings in the Nile delta have not at present yielded any but "derived" fossils; but beds of gravel found at a depth of 120ft. show that the whole surface was formerly 120ft. higher, and was that of an ordinary river valley.

In a memoir on various phenomena presented by the artesian wells recently sunk in Algeria, laid before the Paris Academy of Sciences, M. de Lesseps described the results of some remarkably successful operations carried out in 1885 and last year in the Shotts, where one well, yielding as much as 8,000 litres (1,760 gallons) per minute of pure water, at a temperature of 77° Fahr., had already produced a lake over 32ft. deep, by means of which about 1,800 acres of waste land had been reclaimed. Similar results have been obtained in other parts of Algeria.

The Royal Microscopical Society will hold their anniversary meeting on Wednesday next, February 9th, 8 p.m., at their rooms in King's College, Strand, when an address will be given by the president, Rev. Dr. Dallinger, F.R.S., the subject being "Recent Optical Improvements in the Microscope, and Investigations on the Operation of the Darwinian Law amongst the Minutest Organisms." The address will be fully illustrated by the oxyhydrogen lantern.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of he* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE COMPANION OF RIGEL—ERRATA.

[26784.]—IN 1871 Mr. Burnham discovered the duplicity of H's *comes* to Rigel with his 6in. refractor, the elongation noted being estimated to be in about the direction of 180°. He remarks: "The star was examined subsequently many times with the same aperture, and although there was always a peculiar appearance about the vertical diameter, I could not satisfy myself that it was really double." While examining this star on March 15, 1875, with my 6½in. Calver (being at the time unaware of Mr. Burnham's discovery) I noticed a distinct elongation in the disc of the companion, the direction of the elongation being in 170°—180°, as estimated from a diagram made at the time. Mr. Burnham examined it carefully in 1877 with the 18½in. refractor at Chicago, and was able to measure it on three nights with that instrument in the early part of 1878. The highest power, 925, only gave a small elongation; but that, Mr. Burnham observes, appeared to be well defined and certain. The results of the measures were:

160·3° : : 1878·09 (1 night).
179 0° : [0·35″] : 1878·16 (2 nights).

The central distance was certainly less than 0·2″. From 4 nights' measures with the 6in. refractor at Mt. Hamilton in the autumn of the following year he found,

125·9° : : 1879·68 (4 nights),

noting that "the measures given do not agree with the prior observations, but the slight elongation seemed to be real, and I cannot think there is any mistake." Mr. H. C. Russell appears to have measured the object with the Sydney refractor of 11·3in. aperture; but the observed angles differ very materially from Mr. Burnham's, as Mr. Russell found—

45° ± : 0·25″ ± : 1878·79 (1 night).
64° ± : : 1878·80 (1 night).

He states that when best seen the stars were clearly divided, powers magnifying 600 and 800 times being employed. Professor O. Stone succeeded in obtaining one set of measures in 1879, on a night of magnificent definition, the star appearing "pear-shaped" with a power of 920 on the 11in. refractor. Prof. Stone's results are—

158·7° : [0·42″] : 1879·76 (1 night).

Mr. Burnham examined the star many times in the years 1880, 1881, and 1882 with the Chicago refractor; but could come to no definite result as to its elongation. M. Henry informs me that he has never been able to see the stars divided with the 15in. at Paris; but that the distance is certainly below 0·3″, the mean of three nights' measures in 1884 giving for the position angle—

178·0° : : 1884·14 (3 nights).

In view of the remarkable discrepancies in the observed position angles quoted above, it is desirable that this very interesting object should be examined carefully with such telescopes as the Nice, Washington, and McCormick refractors. M. Henry also informs me that he has succeeded in obtaining photographs of the satellite of Sirius with an exposure of 4 seconds.

In letter 26654, page 410, the R.A. of β 163 should be 21h. 13m. 7·3s., and not 20h. 13m. 7·3s. as printed. In letter 26758, page 476, for "magnitude in the test," read "magnitude in the text."

H. Sadler.

66 CETI (Σ 231) AND Σ 274.

[26785.]—IN my inquiry about the magnitudes of 66 Ceti (letter 26718, p. 451) I find I have made an inexcusable error, and while I offer my best thanks to Mr. Sadler for his kind reply and valuable information concerning it, I must beg him to accept my sincere apologies for the trouble I have unwittingly given him.

The error arose from my mistaking Σ 274 for 66 Ceti (Σ 231). In looking for the latter I inadvertently set the finder on δ Ceti to guide me to it, instead of setting it on Mira. 66 Ceti is 1½° W. of Mira, and Σ 274 is a trifle more on the W. of δ.

The position-angles and distances of these two pairs are not very dissimilar, though a glance will show the disparity in their magnitudes.

While looking at Σ 274, and thinking all the while I had 66 Ceti in view, I was not unnaturally surprised at what I took to be the discordance of magnitudes with those given in "Celestial Objects" and the "Star Guide," and I thought it might be worth a query. Again I express my regret for the mistake.

The particulars given of 66 Ceti in the "Star Guide," page 4, so far as recent observation enables me to judge, seem the refinement of accuracy.

Jan. 28. **H. Dowsett.**

OCCULTATION OF ALDEBARAN.

[26786.]—I HAVE computed the occultation of Aldebaran on January 6 last for latitude 54° 44′ 23″ N. long., 1° 48′ 43″ W., by the partially graphic process of the late Mr. Pearson, and make it 12h. 10m. 38sec. local time for disappearance, and 12h. 57m. 8sec. for reappearance. This is pretty near Mr. Slade's observed time, and although not assumed to be an exact and strictly accurate calculation, yet near enough, as the late Mr. Pearson intended, for a good approximation in aid of actual observation. I make the angles the same as Mr. Slade. **John Bone.**

St. Thomas' Vicarage, Lancaster, Jan. 26.

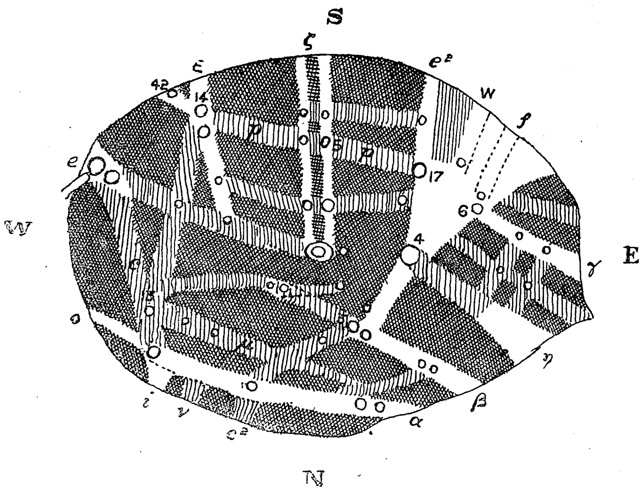
THE MARKINGS ON THE FLOOR OF PLATO.

[26787.]—PROBABLY no portion of the moon's surface has received more assiduous and searching scrutiny than the floor of the walled-plain Plato, a surface roughly circular of about 60 miles in diameter, though from its position it appears to us in the form of an ellipse, and it might, therefore, be thought that the discovery of additional features upon it would be infrequent and confined chiefly to instruments of greater size and power than those which had hitherto been employed upon the object. However, in the course of three nights in the present month with a 6½in. Calver reflector I have succeeded in detecting at least 23 *new* objects—namely, 11 light spots and 12 light streaks—and this notwithstanding that it was rather early in the luni-solar day for securing the best results, and that the weather never remained fine sufficiently long to make an exhaustive examination of the whole of the floor. In addition to the new features, several objects which have been unobserved for years were seen again.

The inclosed drawing of Plato was made on January 8th last between 12h. 30m. and 14h. 0m., with a power of about 170 on the 6½in. Calver. It shows 43 spots and about 32 light streaks. Some parts of the floor, however, received little attention, and this was especially the case with the western quarter. Several of the new features give promise of being rather interesting objects. Thus on the southern portion of the floor will be noticed a plain streak running east and west between spots No. 14 and 17. In the British Association Report, 1872, p. 243, Birt remarked of this streak:—"The observations had proceeded with great care during a period of more than twelve months, when a new streak made its appearance between spots Nos. 5 and 14. Some months afterwards a continuation of this streak eastward of No. 5 was observed, and very lately it has been seen between Nos. 14 and 22." Now immediately south of, and nearly parallel to, this streak, p, between streaks ζ and e^2 a fresh streak will be seen, which on the night in question proved an easy object. It would be interesting if, in a similar manner to p itself, this new streak should afterwards be found between ζ and ε. There is not the slightest trace of any continuation in that direction at present.

Just above the large, bright, central crater will be found two spots lying close together. The easternmost is No. 9, an old and bright spot. The westernmost is a new and by no means difficult object. As it has now been seen on three separate nights, and there is, therefore, no doubt as to its existence and situation, it has been numbered 59.

Between the bright streaks γ and η in the north-east corner, instead of the single streak, b^2, connecting them there are now *two* streaks; whilst also between the two former streaks, and running parallel thereto, is a new streak, which is a plain and easy object.



A continuation of the bright streak β in a westerly direction extends to two spots close together a little N.W. of the central crater. The easternmost of these two spots is No. 0, the westernmost is new. The streak forming the continuation of β has likewise not been seen before. It forms the connecting link between the streak λ (not shown in the drawing) and β. On Jan. 15th, 1870, Mr. Gledhill with the 9½in. refractor of the Bermerside Observatory saw this streak λ, but was unable to see β and λ in the form of one continuous streak.

South of a, o on the north-western portion of the floor the streak μ was a conspicuous object, and could be seen much further east than it has been before, tapering gradually away. On it are at least two spots. The bright streak ζ, south of the central crater, has hitherto only been described as single. It is really, however, composed of two narrow, pretty bright streaks running parallel to each other. As before stated, the western part of the floor was not closely examined, owing to want of time. The interesting streak g^2 extending from spot 13 to 14 was, however, seen to consist of two narrow, parallel streaks close together, somewhat resembling ζ. **A. Stanley Williams.**

"F.R.A.S." AND THE DISCOVERER OF THE ORION PLANETOIDS.

[26788.]—WE all feel sincere compassion for the probably direful fate of our valued correspondent "F.R.A.S." since he has dared to attack Mr. Roberts, of Maghull. The letter of "Another F.R.A.S.," and the prospect of another attack from Mr. R. himself, are so appalling, that it is in fear and trembling that I take up my pen to reply.

Now, Sir, no one will deny that "F.R.A.S." deals hard blows; but they are dealt against either incompetency or humbug, and for my own part I am ready to offer my back at any time should I be guilty of the first—of the latter I trust I never may be guilty.

Now let us see on what grounds Mr. Roberts's knowledge is stigmatised, and justly stigmatised, as imperfect. Mr. Roberts was discovered as a planetoid of the first magnitude in a paper read before the L.A.S. on February 18th, 1884. Although he has never had the courtesy to acknowledge it, his first experiments in photography were made under the guidance of Mr. W. L. Stubbs, who was detached from West Kirby, and taught him the method of developing his plates. Before this time I don't think anybody had ever heard of Mr. Roberts in the astronomical line. At this time he budded in the L.A.S.; two years later he blossomed, to the misfortune of that society, as its president. The results of that session need no comment. The *Journal* speaks for itself. Having been ejected by a majority of votes, he departs to the R.A.S. Mr. Roberts's career, as far as the general public is concerned, dates from 1884 to the present time. He is, therefore, a three-year-old. In such a short time, it is impossible to get any idea of practicable observational work, so that on that ground alone "F. R. A. S." is amply justified in declaring Mr. R.'s knowledge imperfect. But when, in addition to this, a F. R. A. S. makes a learned society and astronomy in England a laughing-stock to the world by discovering a pleasure party of planetoids travelling some 25° from the Ecliptic in the midst of a nebula, I think the word "imperfect" is the very mildest that can be used.

Mr. Roberts' driving clock is perhaps a new one. The one I saw in his observatory caused the tube to jerk perceptibly under a pretty high power.

As regards the actual photographs, it would be interesting to see one of a first-magnitude star, Sirius or Vega. My impression is, they would be found to have as fine a nebula round them as the Pleiades.

In conclusion, I think, Sir, the "E.M." is to be congratulated in having correspondents like "F.R.A.S.," who prevent the public being gulled in the way they otherwise would be; and as to "Another F.R.A.S.," let him persuade Mr. Roberts to obtain the assistance of a competent astronomer for his observatory, and let him do the work while Mr. R. sits smoking his pipe and finding the funds, and by his absence benefiting astronomy in general more than he otherwise ever will do.

A Third F.R.A.S.

FIREBALL — U CYGNI — V CYGNI — COMES TO POLARIS—MARE SERENITATIS — STAR COLOURS AS SEEN WITH DIFFERENT EYES — THE LUNAR RAY SYSTEMS—66 CETI.

[26789.]—ON the evening of the 17th Nov., at 11h. 30m. p.m., I saw an exceedingly fine fireball. It was not well placed for my determining its exact path; but it passed from near θ Ceti, I think, into Lupus—a course extending from about 15°—10° to about 80°—20°. In magnitude it was equal to a first mag. star. Its colour was bluish-white, something like the electric light. It increased in size till it became about one-third of the moon's apparent size. At this point the bluish-white light died out, and was succeeded by a dull glowing red. It did not disappear, but remained visible as a dull red ball. As it passed it varied in brightness, but continued to lose colour. Finally it disappeared, at the same time throwing out a number of dull red sparks.

I am very much obliged to Mr. Tarrant for taking so much trouble *re* U Cygni, more especially for measuring it. I did not expect to find that there would be many measures of it in existence, but I hoped to ascertain whether it was known to exhibit c.p.m., and I am obliged to Mr. Tarrant for the information he has given on this point. There seems to be something specially interesting about the colour of the blue star. I was reminded of this while observing the star on the 22nd Dec., when this was my entry: "A, the richest ruby; equal B; blue of B not very plain, at moments star appeared almost reddish." This brought to mind that Birmingham twice speaks of the blue star as appearing reddish. Under date 1875, Nov. 21, he says, "the blue seems turning reddish," and in the observation immediately following — "1876, Jan. 21 . . . (the blue turned reddish; 8·4)." He says nothing about the blue star in the next observation; but in the next again, April 24, same year, says, "The blue has regained its former colour." Now we learn from what Mr. Tarrant says (p. 368) that Dr. Copeland on one occasion found the star "white," but "blue" just nine days afterwards. Then, again, while we have Mr. Tarrant saying that the "colours were noted in brilliant contrast," and that "with a low power the pair is unquestionably a very fine one of its class" (p. 322); we find, on the other hand, Mr. Espin declaring that he has "never seen the blue colour." With the larger aperture he invariably found "the star" to be yellowish." It would be interesting to know on how many occasions Mr. Espin has observed this star with this result. It is to be noted that Mr. Tarrant's aperture is over 10in., much larger than the 3in. mentioned by Mr. Espin, in which the star had only "a bluish look." It is of importance to try to ascertain the cause of discrepancies such as these, because there is, I think, special reason to suspect variability of tint in this star, and also in a number of other blue stars.

In reference to what Mr. Ward says in letter 26570 (p. 322) about my not seeing V Cygni, I may say that I think it was due to my not being perfectly familiar, from previous observations, with the place of the star. I have not been able to get any recent observations, so cannot report anything further as yet.

In connection with M. Lihou's paper in the L.A.S. *Journal* for Dec. last, it may be of interest to quote from Mr. Honeyburne's paper in the *Journal* for April, 1883:—"Webb calls the companion to the Pole star 9·5, and that to Aldebaran of the 12th magnitude; but the latter is about as easy to me as the former—indeed, there have been nights when I could see Aldebaran's *comes* easily and steadily, and could only glimpse the Pole star's little twinkler." Struve's magnitudes for the *comites* to Polaris and a Tauri are respectively 9 and 11·2, and the "Star Guide's" magnitudes 8·4 and 10·3. But, of course, if the *comes* to Polaris be really variable, it is strange that the fact has not been definitely ascertained before this, seeing that the star is so often examined, and so frequently employed as a test, though, as to this latter matter, variability might explain some of the discrepancies in recorded performances of telescopes. But the circumstance noted in "Celestial Objects," that Dawes proposed it as a general standard, must throw very considerable doubt upon the hypothesis of variability.

Mare Serenitatis.—On the 17th November the Mare was favourably situated, and I examined the inlet from the east. I saw nothing, however, of any dark band such as was mentioned once by Mr. Bone in a letter in "Ours," as passing from Autolycus.

I see that the question of the respective powers of the different eyes in the matter of colour-perception has been brought up at the R.A.S. I have repeated the experiment at intervals, under different conditions, and have never found any difference in the tint of the star arising from the fact that it was being viewed with a different eye. There is sometimes a difference in apparent brightness, but never of tint. The difference in apparent brightness has its origin in the circumstance that, owing to the differing *foci* of my eyes, I observe, as a rule, with the left, and, therefore, when the right is employed it, being less used, is more susceptible to impression. This point is to be noted, for I think it is pretty certain that differences in brightness are sometimes mistaken for differences in hue. The point demands investigation, however: To what extent a difference in colour-perception between the eyes has entered or does enter as a source of error into the records of star-colour observations?

I am much obliged to Mr. Stanley Williams for his letter on p. 431. It is certainly strange that the study of these remarkable features of the lunar surface should have been so generally neglected. I hope that Mr. Williams will see his way to furnish some notes from his own observations, and would be glad if he would add any additional names he may know of to the list of systems which I gave. I think that Mr. Williams has overlooked Mr. Dennet's map of the system of Proclus, which was given in the "E. M." This is, as I have found, an exceedingly accurate map, and it is much to be desired that there were more like it. As to the classification of the rays, I do not so much mean to recommend the classification of *systems* as of *rays*. From my own experience, I conclude that the division into "Tychonic," "Copernican," and "Messier" rays is sufficiently precise to admit of being at least provisionally employed in the description of the rays. I intend to pursue the matter of the rays which I think I have seen coming round from the dark side, with a view of obtaining more definite information; but meanwhile may say that I think that some will be found near the limb of the north-western quadrant.

Mr. Dowsett inquires about 66 Ceti. I have only one observation of this pair, made with 45 upon the 3¼in., on Sept. 19, 1885. A was found to be fine yellow, and B blue. There was not quite one magnitude of difference between the components. This difference, of course, is considerably less than either given in Webb. The star is a suspected variable one, being 58 in Mr. Gore's Catalogue of Sus. Var. Stars. The supposed range of var. is 6—7, on the authority of Taylor. In the notes it is remarked that Dr. Gould finds no evidence in support of var. It is not in *Uran. Nov.*; but is 6—7 in Heis; 5·8, Gould; 7, Harding; 5·64, H.P. It appears, however, from what is stated in the notes, that, while on one occasion Mr. Franks found 66 equal to 63, on another Mr. Gore found the former a half mag. above the latter.

S. Maitland Baird Gemmill.

HORIZONTAL WINDMILLS.

[26790.]—'TIS an old saying that each generation is wiser than the last, and it seems a great pity, for "Medhurst's" sake, that "A., Liverpool," was not present at the trial of the vertical and horizontal mills as related by me, for he doubtless would have pointed out our mistakes in the matter.

His noting my silence on the weight and cost of

the metallic parts is also strange, as I give the cost of the mills I used in ploughing as £5, and in the mill I recommended I put the cost of the metallic parts at about £5, and the labour at £10—only, of course, as a rough estimate; but he appears to have overlooked all this.

I would point out to "L. W. D." that a mill protected from the wind on one side has been tried many times, and always failed.

Each sail of the mill I patented is acted on like the sail of a boat, at one part of a revolution beating up to windward, and on the opposite side going large down the wind. In the other two portions of its revolution, having the wind on the beam, and on the opposite side going large—I think the sailors call it. At all events, a single sail will drive the mill, showing that it gives off power in almost the whole of its revolution, as in the only place where it is head to wind the momentum of the mill carries it over that point, and it immediately gets the wind in a favourable position to drive the mill.

I acknowledge my mistake as to the pressure of the wind at 7 miles per hour; it was given from recollection. I give below Ferguson's table, which may be useful to many readers.

I'll begin at 5 miles as a gentle pleasant wind, giving a pressure of ·112 of a pound.

10 miles	Pleasant brisk gale	·492lb.
15 "		1·107lb.
20 "	Very brisk	1·908lb.
25 "		3·075lb.
30 "	High wind	4·429lb.
35 "		6·027lb.
40 "	Very high	7·872lb.
45 "		9·963lb.
50 "	....	12·300lb.

As this is a storm, I fancy this is far enough in the table. **Philip Vallance.**

CONCERNING THE LUMINIFEROUS ETHER.

[26791.]—IN letter 26675, page 414, "Sigma" suggests that there may be nothing in space, excepting matter in an ultra-gaseous condition—that is to say, gas at an excessively low pressure. We know, however, that the velocity of transmission of wave motion in a gas is altogether independent of the pressure, because any change of pressure alters the density and elasticity of a gas in the same ratio, and hence does not change the expression—

$$\sqrt{\frac{E}{D}}$$

Therefore, ultra-gaseous matter could not transmit wave-motion at the rate of 186,000 miles per second. This, however, is known to be the velocity of light, and we are perfectly justified in asserting that it cannot be transmitted by ultra-gaseous matter. My friend says that we know there is something which transmits light, and that is an end of our *knowledge*. In my opinion we know a good deal more; we know the rate of transmission, and from this we can deduce conclusions as to the nature of the substance. "Sigma" does not reply to my argument derived from the prediction of conical refraction and the verification thereof; it is, at least, curious if an utterly erroneous theory led to so accurate a conclusion. Again, the ratio between the electro-static and electro-magnetic units is of the dimensions of velocity, and this ratio, as determined in very different ways by various scientists, is the known velocity of light; and this brings me to remark that "A. X.," letter 26720, page 451, seems to be unaware of the theory developed by Clerk-Maxwell to the effect that electricity is itself a movement in the ether. Certain mathematical deductions have been made from this theory, and are found to be in accordance with fact. Coming now to the letter from Mr. A. Treyer Evans (same page), I really cannot see that quotations from old Hebrew writings have the slightest bearing on any question in science, and, further, I decidedly object to human beings being called "worms." It is sincerely to be hoped that "Abergwili" (letter 26720) will, in the interests of common sense, keep his ideas as to the disappearance of carbon dioxide viâ the luminiferous ether, to himself.

Wm. John Grey, F.C.S.,
Newcastle-on-Tyne. Analytical Chemist.

BURNT AIR.

[26792.]—WITH reference to the subject of "burnt air" (which expression, by the way, is a solecism), touched on last week by Mr. W. Archdeacon in your columns, the evil does partly arise from the decomposition by burning of the dust floating in the air; but the atmosphere contains, in addition to a mechanical mixture of oxygen and nitrogen and a small percentage of carbonic acid gas, a varying quantity of moisture; and hereby hangs a tale.

This moisture, when brought in contact with iron or any metallic surfaces heated much over the boiling point of water, is decomposed into its constituent elements, oxygen and hydrogen; the oxygen forming an oxide with the metal and the hydrogen remaining free. Now, the effects of breathing hydrogen gas are exceedingly injurious, for it produces, amongst other symptoms, difficulty of breathing, followed by abundant perspiration, tremor of the body, heat, nausea, and violent headache; the vision becomes indistinct and the hearing confused.

Another injurious effect produced by the highly heated surfaces arises from the greatly increased capacity for moisture which it produces on the air, which capacity increases with the temperature; but when air is artificially heated without being in contact with water, it is prevented from acquiring this additional quantity of vapour, and it then feels harsh and arid, and is exceedingly injurious to the animal economy. When received into the lungs it causes excessive pulmonary discharge. In addition to this the air rapidly absorbs the moisture from the skin, and this, by its refrigerating effects, contracts the blood vessels at the surface, and leads to other complications. These are only a few of its many physiological ill-effects.

In slow-combustion coke stoves carbonic oxide gas often escapes into the room, because the draught is not rapid enough to carry it off through the flue. **J. Q. D.**

[26793.]—IN connection with Wm. Archdeacon's letter (26772, No. 1,140), allow me to say he has made a slight mistake. CO, carbonic oxide, is extremely rare in air and very poisonous. CO_2 (carbon dioxide, or carbonic acid) is common (4 per cent. is, however, about the maximum) and is not poisonous, except that it will not support life. **Londiniensis.**

[26794.]—IN Mr. Archdeacon's letter (26772) he is mistaken in his formulæ, as he calls carbonic anhydride CO, and carbonic oxide CO_2, the reverse being, of course, the correct formulæ. In this way he has got into a muddle in his statement that the "air consists of a mechanical mixture of nitrogen, oxygen, and carbonic acid"; so it does, but not of a mixture of N, O, and CO, or we might be blown up alive! CO_2 (carbonic anhydride) happens to be rather a stable gas, so that it would not decompose as he suggests unless heated to 1,200°—1,300°, when it is partially decomposed into oxygen and carbon monoxide. Under these circumstances, I am afraid he must have recourse to the burnt-dust hypothesis, unless some deteriorating effect is produced by the heated iron.

Magd. Coll., Oxon. **R. A. R. Bennett.**

THE ACHROMATISM OF LENSES.

[26795.]—IN letter 26759 your valued correspondent, "O. V.," gives as the common approximate formula for achromatising two separate lenses as $\delta = \frac{(F - s)^2}{f F}$, where s is the distance between them. Would he kindly refer us to some authority where this is to be found?—for I think that it will be seen that a much more correct one will be $\delta = \frac{s - F}{f - s}$, δ being the ratio of the dispersive powers. This latter expression is found as follows: The usual formula for s is, approximately,

$$s = \frac{w_1 F + w_2 f}{w_1 + w_2}.$$

Divide numer. and denom. by w, and put $\frac{w_2}{w_1} = \delta$ and it becomes $s = \frac{F + \delta}{1 + \delta}$, which gives $\delta = \frac{s - F}{f_1 - s}$.

As a test of the correctness of the formula which we are objecting to, let us suppose the glasses to have the same dispersive power, so that $\delta = 1$, and the formula will give $s = F \mp \sqrt{Ff}$, whereas its true value is $\frac{F + f}{2}$.

With regard to the novel form of object-glass mentioned by "F. R. A. S.," I am quite as unable as "O. V." is to find any imaginary combination of any two lenses forming an eyepiece, with a small one in front, that will produce anything at all like a good correction; but for all that, such there may be, for if the new glass transmits four times the quantity of light that the usual sorts do, it is plainly a *miraculous* glass, and if we can believe one miracle of it, it is not difficult to believe that it may perform two. **W. G. P.**

A VERY NOVEL FORM OF OBJECT-GLASS.

[26796.]—I REGRET very much not having seen the letter of "F.R.A.S." (26685) for some days after it appeared, or I would have written sooner. It is proposed to correct the aberrations of a single crown glass o.g. by means of a small lens placed in front of the eyepiece, which seems to be virtually the same thing as using an e.p. of three lenses for the correction of the o.g. What we want is, of course, that the final image presented to the eye shall be as free from aberrations as possible. This is usually done by making each of the aberrations—viz., those of the o.g. and of the e.p.—individually as small as possible. But the proposed plan seems to be not to minimise either the one or the other, but to make them such as to destroy each other in the image presented to the eyes.

One would think at first sight that, considering the number of arbitrary qualities we have, this might theoretically be done; but what the practical difficulties may be is not so easy to say, without examining some particular cases. Most persons will suspect that it cannot be done.

Moreover, supposing that a given arrangement of curves and distances, which give an e.p. of, say, ½in. focal length, will correct the aberrations, it is plain that to get an e.p. of ¼in. to do the same we must have a different arrangement, and not a similar one of one half the dimensions of the other.

It seems, too, if I rightly understand, that by the new plan exactly four times the quantity of light reaches the eye compared with what usually does, which seems to be a complete "staggerer."

W. G. Penny.
6, Alexandra Villas, Redhill, Jan. 25.

NOTES ON THE CHURCH ORGAN.—TO MR. G. A. AUDSLEY, F.R.I.B.A.

[26797.]—I THANKFULLY accept your kind invitation to further discussion on the subject of the upper partials. I have no doubt that I have fallen into an error, probably caused by neglecting to allow for the inevitable "wolf"; but I reasoned (if reasoning it can be called) in this way:—I regarded the series of upper partials as describing a sort of tonal hyperbolic curve; well, when you pass from c''' to d''' and then on to e''', this curve appears to be obliterated in favour of a straight line, because the intervals between c''' and d''' and d''' and e''' are the same—viz., a whole tone.

Again, the number of vibrations you quote for e'''—viz., 2,560—I make 2,592, arrived at in this way:—I considered the ratio in number of vibrations for any note, compared to its major fifth above, to be as 2 is to 3; working up this, therefore, from C = 512 will land you at 2,592 for e'''. So, also, regarding from c''' to d''' as one whole tone, and d''' to e''' as a similar whole tone, we get:—

$$\begin{matrix} c''' & & d''' & & d''' & & e''' \\ \text{as } 2{,}048 & : & 2{,}304 & :: & 2{,}304 & : & 2{,}592; \end{matrix}$$

but as it is quite clear you know ten times as much of the whole subject as I do, I should have been quite content to have accepted your very kind statement (reply 61441, p. 464).

I conclude that the ear demands for musical satisfaction that the major third above keynote shall be rather flat, or, in other words, make a less number of vibrations than would appear from my method (no doubt false) of reasoning to be due to it.

I have an organ pipe about a couple of feet long, and little more than ½in. diameter. With this it is easy to blow with the mouth not only the fundamental note, but all the partials up to the ninth, and with a little practice all the bugle calls so familiar to those residing in a military town like this (Plymouth) can be easily imitated; I dare say you have tried this yourself, and I mention it principally for the benefit of other readers, as it is a pretty and interesting experiment.

Devon. **C. R. O.**

NON-FLESH DIET AND HARD WORK.

[26798.] — I WISH everyone would write as sensibly and temperately as our friend "Os," 26764, p. 477, on these subjects; but "faddists" would restore the Inquisition for unbelievers in their theories if they could.

My diet is very similar to that of "Os," and I get through a fair amount of both mental and bodily work thereon; but, notwithstanding, I find people constantly insisting, on the one hand, on the necessity of eating more meat and drinking more wine, and, on the other, of abstaining from both altogether.

I remember once placing one of these latter gentry, with myself, before a mirror, and asking if we should be taken for twins? "Certainly not," replied he, "there is no likeness between us." "Then," said I, "why can't you understand that there may be precisely the same difference internally as externally"? This spiked his gun.

B. Harcourt.

LATHE MATTERS.

[26799.]—MY thanks to "F. A. M." But the designs in Holtzapffel's Vol. IV., though admirable as exercises, belong to a period of taste that is, I

trust, passing away for ever. The general impression left on my mind by them is that they are the work of a clever man anxious to show off his tool and his command of it. Now, I maintain that this is inverting the proper order of all good designing, and that the important problem for the artist is, granted some requirement, to choose the right material and the right methods, and then devise pleasing and suitable forms.

Designs of this character can be found, and it would, I make no doubt, be a help to many artistically and mechanically if those who chanced to find or originate them would put them on record, and, indeed, there have been previous suggestions of the sort in the "E.M." I have already sought inspiration at Tunbridge Wells, and duly admired certain humming-tops, a plain platter, and a pincushion about the size of a crown-piece at the Tunbridge ware factory, but shall keep from picking and stealing nevertheless.

However, for turned-work on a small scale, metal, especially brass and other bronzes, is usually much more satisfactory in the end than other materials, as the objectionable flat appearance which is common on dead surfaces is destroyed by the reflections on the polished metal. At the present time I could lay my fingers on several charming designs; but it will be long before I could give particulars of patterns and core prints with confidence of accuracy sufficient for the use of brother amateurs. For instance, I have within reach a very nice old pattern of candlestick, quite old enough to be public property, and would gladly give an *accurate* drawing of the complete article, and *approximate* drawings of patterns and core prints to anyone who would be at the pains to work them out and correct them for the benefit of the "E.M." I do not for one minute wish to depreciate the inventive skill of "F. A. M." and others; but I think we are backward in applying its benefits to practical purposes. **W. A. S. B.**

LATHE MATTERS.

[26800.]—MY attention has been drawn to "F. A. M.'s" letter, No. 26704, "E. M." of the 14th inst. Probably you will be aware that the geometric lathe was offered for sale on the 17th ult., and we bought it in at £340, not having reached the reserved £350. We should prefer to dispose of the manuscript, drawings, and specimens along with the lathe. Father intended (had he lived) to publish the book on "Geometric Turning," &c., and had a list of 200 (unsolicited) subscribers. We should be very glad to show the lathe to any likely purchaser.

Salford, Jan. 31. **Alf. Hartley.**

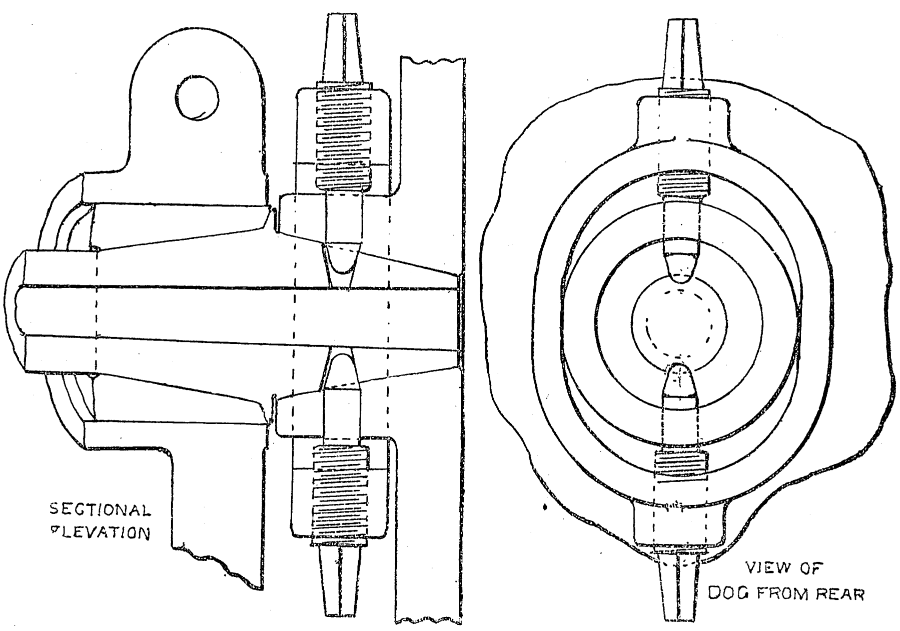
"F. A. M's." LATHE DESIGN.

[26801.]—IN glancing at the drawing of the above (in the number for September 24th, 1886), my attention was drawn to two minor points of interest. One is the oiling arrangement for the sliding bushes. I do not think sufficient provision is made to keep the surface of the mandrel oiled by cutting a groove round the bush and making a hole into the interior. It would be better, I think, to either make a spiral groove round the exterior of the bush, of about ½in. pitch, and with a number of small holes—say, $\frac{1}{16}$in.—leading into the interior, or to cut two or three small grooves round the exterior, drill opposite holes in them to interior, preferably small holes, and to cut a channel in the headstock to lead the oil from the oil-hole into all the grooves. To protect the sliding bush, I am inclined to think a temporary, or removable, boss on inner side of headstock would be better than an extension of casting.

To get the mandrel in and out with a shoulder at front of less diameter than collar, it is not necessary to disturb the pulley and division plate. If the pinion is made to slide up to cone, the removal of the back bush will enable the front one to be shot inwards, and the mandrel, &c., to be taken out sideways. By fixing the cone about 1¼in. back, the front bearing, &c., could be examined at any time without other disturbance of parts than that of the nuts behind. **Vulcan.**

MANDREL NOSE.

[26802.]—THE accompanying drawing is of a coned nose, specially schemed for suitability to 'F. A. M.'s" lathe design. It has many advantages, and the method of attachment is new, I believe. I believe also the arrangement would be found to give much satisfaction in working. For common chucks, two tapped holes in bosses might replace the dog; but the dog is put in to give an even grip at each side of cone, and so settle it truly and with even firmness. The large clear at each screw of dog from boss is to allow easy manipulation; in using, one screw is set to its place when home, and the other screwed out to clear; the dog then allows the screw that is set to be pushed clear, and leave the coned hole free to be put on nose; the chuck or plate can then be put on with both hands, held in place with one while the dog is pulled till the



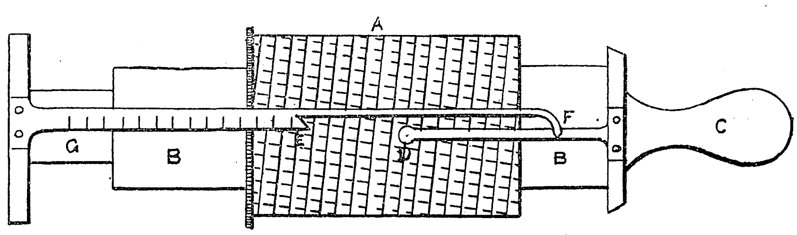
pin that is set enters, when both hands are free. A few turns of the other screw, and a very little nipping with a small, neat key, then sets the plate on the nose. This arrangement would be found very handy, and one dog and pins might be used for several articles. One for each article in frequent use is intended, however. The points in favour of the nose are (1) it is very strong; (2) the overhang is quite moderate, while the bearing is plentiful; (3) there is no movement under pressure on the nose, so a spring temper, or even a soft one, would be very durable; (4) it has, like the key, the advantage of set position and capacity to drive each way securely; (5) it is not unreasonably difficult to make. The taper holes are drilled while the nose is cylindrical, and reamed taper. They are in a belt of slightly reduced size round the cone, so as not to interfere with grinding true. A coarse thread on the set-pins in dog would give wear and quick action; but a thread $\frac{1}{32}$ or so at bottom diam., such as is shown, and that will leave that diameter of plain shank to go through boss, will be found good. For very nice working, both screws would need a little turn with the spanner, as the rotating screw would enter a little more easily than the set one. The dog shown is selected from quite a number of similar devices, as being the one most likely to suit all round. The contact of the dog with the boss is advisable, hence its elongated form, which checks the tendency to twist or wobble; a ring would be easier to make, but would spring more and get across. **Vulcan.**

ELECTRIC LOCKING.—TO J. DIXON.

[26803.]—I AM greatly interested in electric locking; but I must say I agree with J. Dixon (p. 480), for after reading Mr. Spagnoletti's explanation (26727) we are no wiser. "Rover," J. Dixon, and C. E. Stretton all point out that **you** must *first put your lever back before you can lock it*. Well, if that is so there is no safety in the system. If one man does not return his lever you cannot lock it, and all the electric catch lock, &c., is of no avail; it fails to do just what it should do. I join with others in asking Mr. Spagnoletti to give us a clear description of his invention. **Electric.**

PROFESSOR FULLER'S SPIRAL SLIDE RULE.

[26804.]—SOME time ago a correspondent asked for working drawings of this spiral slide rule. As none have yet appeared I send a rough sketch of the instrument, which may be of use to some of "our" ingenious mechanics. It consists of a cylinder A which can be moved up and down and turned round, sliding stiffly on an axis B, which is held by a handle C. On the cylinder A is wound in a spiral a single logarithmic scale. Fixed to the handle is the index D. The other indices, E and F, whose distance apart is the axial length of the complete spiral, are fixed to cylinder G. This cylinder slides in B like a telescope tube, and thus enables the operator to place the indices in any required position. Besides the ordinary operations of multiplication and division, the reciprocals, powers, roots, and logarithms of numbers can be easily and quickly obtained by this admirable instrument, the length of the scale being 500 inches, and the number of divisions 7,250. The method



of using it will be found on page 424 of Vol. XLIII. **Reymond.**

FAST TRAINS.

[26805.]—SIR O. H. P. SCOURFIELD asks (p. 479, 26774) why, if Midland engine 1568, with 18 by 26 cylinders, can run on a nice falling gradient from Luton to St. Alban's at 77 miles an hour, a Great Western engine cannot run a far greater speed on the G.W.Ry. The reply is clear: it depends on tractive force. If 18 by 26 cylinders can do no more work than 18 by 24, what advantage is there in big engines or long strokes? There *is* a difficulty with G.W. No. 10 on sharp curves. It is true she is not so long as the G.N. 7ft. 6in. singles, but then the G.N. engines have radial leading axle-boxes. **Loco.**

[26806.]—IN reply to Sir O. H. P. Scourfield, the distance from Luton to St. Albans is 10 miles 35 chains, and it is *never* run in less than 9¼ minutes, and generally 10 or 11 minutes. **M. R.**

THE results of the new censuses of France and Germany show a marked falling-off in the rate of increase. In the case of France the rate of increase was low enough before; now it threatens to stop altogether, and in many departments there has been a considerable decrease. The addition to the population in five years has only been 213,857, bringing the total up to 37,885,905. This is equal to an annual rate of only 0·1 per cent. per annum. Germany is not quite so bad, but the rate of increase between 1870 and 1880 was abnormally high. The population by the latest returns is 46,844,926, as compared with 45,234,061 five years before; giving an annual rate of increase of 0·71 per cent. per annum in 1880-85, as compared with 1·14 per cent. per annum in the previous five years.

THE amount of cobalt oxide produced in America in 1885 was 8,423lb., valued at 19,373dol. The total value of cobalt in ore, matte, and the above oxide was 65,373dol.

REPLIES TO QUERIES.

** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[60904.]—**Lilium Auratum (U.Q.)**—I do not think it would "injure the bulb" to ripen either one or the whole of the seed-pods left on the flower stem after blooming. In the first case, all the nourishment from the bulb would get concentrated into *one* seed-pod; whereas, in the other it would be distributed among the whole of them. The best plan is to allow only one pod to remain on the flower stem, and let that one be the *lowest* on the flower stem (the one nearest the soil); seed ripened here generally stand the best chance of germinating into good plants, with care. I suppose I hardly need inform "Hortus" that it is a difficult matter to raise lilies from seed? One of the chief requisites is a good stock of patience; the seed seems such an awful time germinating, however good and strong it may be. Again, the soil must not be disturbed for a whole year, at least, *after* the seedlings have appeared. As an instance of time taken in germinating, I might mention *Lilium giganteum*, which does not germinate until the second year of planting, and sometimes the third. The best and quickest method, however, is to take advantage of the fact that all lilies, speaking generally, may be multiplied by *division*. After the leaves have died down, pull the scales from the bulb, every scale, if desired, will make a new plant. Insert each scale, with its base downwards, into a mixture of sand and fine peat, and assist for a time with the greenhouse. Some varieties produce bulblets (little bulbs) on the flower stem; these fall off, take root, and thus increase one's stock. To produce these, pinch out the flower buds as soon as they appear; which will cause the flower stems to form these bulblets in great numbers in the axils of the leaves. I have not possessed, nor seen, any of these varieties myself, but have read of them.—WILHELM HEINRICH KOPE, Birmingham.

[60987.]—**Organ Query.**—In reply to "A. C." and "J.," I beg to say that the fourteen bottom notes of the stop diap. are ranged in a line along the back of the organ, the lowest four pipes being rollered off. The depth of the case, including keyboard is 2ft. 6in.; length of bellows, 3ft. 4½in.; depth, 1ft. 6in.; and the reservoir rises 7½in. when full. There are foot and hand blowers, both detachable when required; there is no octave coupler, but ample room for one. Length of windchest is 3ft. 10in., and depth 1ft. 3in. There is no separate building frame, as the case is quite strong enough to support bellows, windchest, &c., and the sliders are worked from the middle of soundboard, instead of the sides. As will be seen, the pipes are already inclosed on three sides, so that to have a swell the organ needs only to have a board covering the top and the swelling arrangement. I have adopted the gridiron principle, which consists of two wooden gratings, the one movable and the other fixed; these are placed in position immediately behind the front show-pipes, and worked with the left foot. The pallets and pull-downs are at the back of soundboard, instead of the front, and communicate with the keys by means of back-falls, the near end of back fall (through which is a thumb-screw wire for adjustment) resting upon the far end of key. The case is of mahogany, ebonised and gilt, and each piece of the same fits into its neighbour by means of pegs and holes; screws are only used for fixing bellows, keyboard, &c.—T. D.

[61018.]—**Optical Lantern (U.Q.)**—The only function of the condensers is to concentrate the light from the illuminant upon the picture. The lenses project a representation of the picture upon the screen, and so may be of any focus without regard to the condensers. You may have portrait lenses for any of the foci you mention; but will find that single lenses will be very much cheaper and practically quite as useful.—G. J.

[61048.] — **Electric Conductors.** — I am obliged to Mr. Lancaster for his reply to this query; but beg to be allowed to ask a little explanation of his table. (1) Am I to understand the figures under "Size of conductors, B. W. G." to mean 19 wires of 16 gauge, &c.? (2) What is meant by "The current per square in. section of conductors is 1,400 to 1,700?" With these points cleared up, I will try and understand the rest, and be thankful.—ACIER.

[61131.]—**Electric Cautery.**—My contention that the formulæ (p. 395) is useless so far as this query is concerned, must be either right or wrong. At page 481, "A. D. S." says he is perfectly able to use it. Now, if he will demonstrate in "Ours" how by means of this formulæ he could determine the current necessary to heat his cautery, I shall then at once admit my error. As regards my making any attack upon the medical profession, I fail to see it: it was "A. D. S." who deplored his being in the hands of others. And the need for my objection to Mr. Conry's remarks about using Leclanché cells for cautery purposes is again supported by the remarks of "A. D. S.," and if he had taken Mr. C.'s advice and procured Sprague's "Electricity," he would soon have found there would be no economy in using the Leclanché battery, and as regards its being satisfactory for cautery work, I hope we may soon have this settled. "A. D. S." shows us how doctors differ (queries 61400 and 61399). I have explained my slip in the former, but in the latter I don't see where I have erred. It is wonderful how easily we notice the slips of others, and I have no doubt the slip made by Lancaster in the former query was due to his forgetting that the water—viz., 1,500 tons, required 24 hours to fall. $\frac{1500 \text{ tons} \times 2240\text{lb.} \times 40\text{ft.}}{33000} = 4072$, or nearly what "Lancaster" stated; but $4{,}072 \div 1{,}440$ minutes $= 2{\cdot}85$H.P. per minute. This being a simple arithmetical question, "A. D. S." might easily have seen how the mistake arose. Curious the learned doctor did not see a case where doctors differed almost as much, and when a query addressed to himself by another in the profession has never been replied too; I refer to page 372, query 60982. This, of course, was not a simple arithmetical question.—OHM.

[61131.] — **Electric Cautery.** — TO MR. DUNLOP STEWART.—You have slightly misread one part (not very material) of my last reply hereon. I did not say that the same Leclanchés that would heat the bit of wire I particularised would light incandescent lamps for 20 minutes; but that this could be done with Leclanchés. I mentioned the matter merely as a curious result of a chance experiment. "Ohm's" offer to put down a sum of money as a stake, to be forfeited to me if I can perform the above experiment under certain arbitrary conditions laid down by himself, and which, as he very well knows, would render its performance impossible, is so overpoweringly generous that I do not feel myself worthy to take advantage of it. As a matter of fact, the experiment was performed with three batteries of Leclanché cells, coupled partly in series and partly in parallel, and a switchboard, so arranged that when the first battery began to fail the lamp could be switched on to the second, and from the second on to the third, and then back to the first, which had by that time recovered considerably. With this arrangement it was found possible to keep the light up for more than 20 minutes. Such an apparatus might be useful for furnishing a light by the aid of which to go to bed, or dress on a dark morning, or some similar purpose requiring a light for a short period only; but that is all. Its one merit is that it requires no attention or daily recharging. The measurement of the current which you refer to can only be done by the help of an ammeter of some sort. Mr. S. Bottone has kindly offered to allow me to test his 5s. ammeters, which he says will register from 5amp. to $\frac{1}{10}$ of an amp., and I have arranged to meet him at the end of the week for this purpose. I do not suppose Mr. Bottone would claim anything he was not certain of, and if my hopes in this respect are realised, I should certainly suggest your using these, for $\frac{1}{10}$ of an ampère is a close measurement, and you might easily pay, among the electrical apparatus shops, three times that price for an instrument not half as good, as I have done, to my sorrow, before now. —EDWARD CONRY.

[61138.]—**Yacht Steering.**—I have a steering gear that will, I think, just suit "G. H. V." It is simple, strong, and takes very little room. The tiller can be used as usual; but when extra power is required (without making any alteration, but simply raising the hand about 6in.), the power can be increased from four to eight times. As I think of patenting the arrangement, I cannot send drawings yet; but will, if the Editor thinks it of sufficient general interest, in the course of a week or two. If "G. H. V." will advertise his address I will communicate with him.—S. BEECHING (late Bombay Marines).

[61138.]—**Yacht Steering.**—As this query has not been satisfactorily answered by abler correspondents, I will advise "G. H. V." not to try any such "'long-shore" tricks as balancing his rudder, or substituting any machinery whatever for the simple and effective tiller; for so sure as he does it will "sell him a dorg," as the saying is, and "fetch away" the very first popple he gets into. If there is such a drag upon the rudder that a moderately short tiller with the assistance of the tiller ropes will not control it, why there is something radically wrong in the trim of the vessel, be it large or small; and when you consider that this pressure on the rudder means so much drag on the boat, and not only decreases her speed materially, but makes her "steer dead," you will find your wisest course is to put on headsail, or take a cloth or so out of the mainsail, if a cutter; and if a small yawl, knock out the mizen at any price. Failing this, the only practical thing I know of is a wheel, and this is more fit for a large yacht or steamer than small craft, which are often more lively than the wheel itself.—H. S.

[61145.]—**Does it Boil?**—Has "Weald" ever seen a cup of cold water steaming in frosty air? Knowing that visible steam is not vapour, but consists of minute liquid drops, how does he account for their presence on the "solution" hypothesis? Water vapour is lighter than air, CO_2 heavier; therefore, the water vapour will diffuse itself through the air rapidly as it is formed, the CO_2 will do so more rapidly; but I said nothing inconsistent with the fact that while the vapour is being evolved it will more or less replace air in a flask. If "Weald" will read up the subject, try a few experiments, and take a month to digest, and allow for mental inertia, he will be in a better position to test the value of his hypothesis.—W. A. S. B.

[61145.]—**Does it Boil?**—TO "REYMOND."—Vide my own remarks last week. As regards yourself and "W. A. S. B.," and any others who feel challenged by my imputing to the vapour from boiling water a "displacing" action, my feeling is that anyone who has failed to recognise such displacement or repression of atmo., at least as an initial action, howsoever disguised by subsequent or simultaneous diffusion, or by the conversion of the vapour (gaseous H_2O) into visible steam (liquid H_2O), has yet to learn what the quality of boiling is. Hitherto he has merely understood that boiling is a bubbling turmoil provoked by heat, and that the process commences when the water attains a particular temp. varying according to pressure. But why the same water which in the attenuated air of an air-pump receiver will boil when it reaches, say, 20° C., will not boil in natural air till it reaches about 100° C., this is a matter which he can never have sought to penetrate, and hence he lives in ignorance as to internal condition that constitutes boiling. Glad if these my advisers, as reward of kind desire to help me, may reap some useful instruction for themselves. However, the precise reason why water will not boil at standard pressure till it reaches 100° C. is that at any lower temp. its expansive stress (or elastic force, or molecular energy, or &c.), will not enable it to hold its own as vapour against the pressure above —e.g., vapour at 20° C., filling a flask placed under receiver, would collapse into liquid if standard pressure were restored. The hotter the water the greater its expansive stress, and when this is great enough the atmo. yields and "displacing" vapour bursts forth.—WEALD.

[61153.]—**Blowing Fan.**—Dr. Carl Hartman, in his "Berg und Hütteningenieur," gives the following rate for velocity of air through blast nozzles under given w.g. pressures:—

$$C = 125\sqrt{H} \text{ mètre.}$$

In which—

C = velocity in mètres per second.
H = w.g. in mètres.

Thus, the velocity of air through a nozzle under a w.g. of 0·200 mètre (7⅞in.) would be

$$125\sqrt{0{\cdot}200} = 55{\cdot}9 \text{ mètres.}$$
(or $55{\cdot}9 \times 3{\cdot}2809 = 183{\cdot}4$ft.) per second.

The same result would be obtained by substituting the height of a column of air equal to this purpose, and calculating the velocity as per rule for falling bodies. The equivalent air column is 800 times as high as that of the w.g. column, or $0{\cdot}200 \times 800$ = 160 mètres, or 525ft., and—

$$8{\cdot}02\sqrt{525} = 183{\cdot}7\text{ft. per second.}$$

The formula for volume is as per same authority—

$$M = 0{\cdot}85 \times 125 \times a\sqrt{H} \text{ cubic mètres.}$$

Thus, if a = area of tuyere, say, for 38mm. diam. (1½in.), and H as above = 0·200 mètre, and ·85 = coefficient, then—

$$0{\cdot}85 \times 125 \times {\cdot}00113 \times \sqrt{0{\cdot}200} = {\cdot}05364095 \text{ cubic mètres per second.}$$

Or—

$$3{\cdot}2184 \text{ cubic mètres } (3{\cdot}2184 \times 35{\cdot}3 = 113{\cdot}6 \text{ cubic feet) per minute.}$$

A more concise rule (taking coefficient into the formula, and giving result in cubic mètres per minute) is the following:—

$$Mm = 5004d^2\sqrt{H} \text{ cubic mètres.}$$

In which d = diameter of tuyere in mètres, H as before, and Mm volume in cubic mètres per minute. The work in the air at exit is calculated by the formula—

$$E = \frac{1{,}000\ M\ H}{75}$$

i.e., the H.P. (metric H.P. = 542·47 foot-pounds per second) is—

$$\frac{1000 \times {\cdot}05364 \times 0{\cdot}200}{75} = 0{\cdot}143.$$

Ordinary well made blast fans yield a useful effect of about 40 per cent.; therefore, H.P. required as motive power to drive fan for one such tuyere = 0·357. Would some of our friends supply particulars of proportions of fans for given work (volumes, pressures, powers, &c.), or for fires,

cupola melting, and ventilation? There seems as many different proportions as there are makers, and it would be a great satisfaction doubtless to many readers to have some correct standard to compare makers' statements with.—MARIENBERG.

[61154.]—**Lens Measurement (U.Q.)**—A $\frac{5}{8}$in. stop to a lens of 6½in. focus = $\frac{f}{10 \cdot 4}$ as follows: $6\frac{1}{2} \div \frac{5}{8} = \frac{13}{2} \times \frac{8}{5} = \frac{52}{5} = 10 \cdot 4$.—G. J.

[61161.]—**Converging Lenses (U.Q.)**—It is immaterial which sort of lens is used, the object being to direct the beam of light, after crossing at the focus of the lens, upon the mirrors. See "Ganot's Physics."—G. J.

[61167.]—**Water Tanks (U.Q.)**.—Divide the number of gallons a tank is to contain by 6¼ to get the number of cubic feet in the tank. The sizes of parallelopipeds can easily be determined according to choice; thus, say one to contain 1,000 gallons = say. 160c.ft., then tank may be 6ft. by 6ft. by 4ft. 6in. = 162c.ft. — sufficiently near. For a tank the frustum of a cone in shape of the same capacity all depends on the shape of the cone; but assuming a right cone, and that the frustum is half the height of the whole cone, suppose this frustum to be 4ft. 6in. high as in the preceding example, then tank might be 8ft. 8in. diameter at bottom and 4ft. 4in. diameter at top, which would give about 162 cubic feet contents; thus cube contents of whole cone = 8ft. 8in. × 8ft 8in. × ·7854 × $\frac{9}{3}$ =177 nearly, less frustum 4ft. 4in. × 4ft. 4in. × ·7854 × $\frac{\text{4ft. 6in.}}{3}$ = 15 nearly = 162c.ft.—G. J.

[61190.]—**Differential Feed.** — ERRATUM.— Read (12 + 20) : 20 = 32 : 20 instead of what is printed. Remaining portion is correct.— T. C., Bristol.

[61190.]—**Differential Feed.**—This subject is one which few in workshops understand, and "T. C., Bristol," in his last reply, has answered one question incompletely and another only approximately. I have thought out the subject, and come to the following short rules:—1. Multiply the pitch required by the number of threads in the screw. This will very probably be a fraction. For a right-handed screw, 2*a*, substract from this fraction (from 1) unity, and this will give the ratio of driving wheel to driven. For a left-handed screw, 2*b*, subtract the fraction (from 1) from unity, and this gives the ratio of driver to driven as before. It is to be noticed that the ratio obtained may be that of the *product* of the drivers and product of driven wheels—e.g., in the query to cut a pitch 0·148in. with a left-handed screw of four threads per in.—

$$0 \cdot 148 \times 4 = 0 \cdot 592,$$
$$1 - 0 \cdot 592 = 0 \cdot 408;$$

therefore, 408 to 1,000 is the ratio required, or 51 × 2 to 50 × 5, or a 51 wheel driving a 50 corresponding to A driving B (see ENGLISH MECHANIC, No. 1134), and a 20 driving a 50 corresponding to G driving D. This gives the pitch exactly, and for a left-handed screw as asked. With a right-handed screw, and using an even number of idle wheels, 49 driving 25 and 65 driving 50, we obtain 0·1481 pitch, which is a trifle nearer than "T. C.'s" pitch of 0·15626, using 130 and 80. An even number of idle wheels should be used except in special cases where with a left-hand screw the pitch required is greater than the pitch of the screw. When this is the case, Rule 2*b* is modified, and 2*c* add unity to the fraction (from 1), &c. This gives, in the case of three threads, the wheels 120 and 40, using, however, an odd number of idle wheels, without which six threads will be cut, and not three.—R. T. S.

[61202.]—**Fret Saws Breaking.**—I did not see the question till my attention was called to it by Saml. Ray's answer last week, or I would have replied before. You must be careful not to press too hard, especially when cutting straight; as there is more temptation to do so when you see a plain bit of work in front of you. You must be also very careful not to let the work jump. Perhaps you run the machine too fast, a very slow rate is quite fast enough. Try setting your saw looser or tighter, and try some thinner stuff at first, since you say you are a novice. What size saws do you use? Perhaps some alteration in that direction would make a difference, although I always use a fine saw, No. 1, no matter what the work is. I have done fretwork for over six years now; but I always use an ordinary 12in. hand frame. I can work better with it, and, strange to say, faster than I can with a machine. I should not advocate making the saw describe an arc if you want to turn out clean work, as I have always found that it leaves the marks of the saw in the wood more than a straight up and down motion; and, besides, you are either putting an undue amount of pressure on the middle of the saw, or else not using the ends so as to make them do their share of the work. Saws often break from being tempered badly. You often find some good and others no good at all in the same dozen. I believe sometimes they will break from one of the teeth being cut too deep in the making, but am not sure. Have you tried the "Griffith saw"? They are very good for straight, rough work; but I fancy they tear the wood too much for fine work. If you like to give your address, I will send you one or two to try.—HARRY FRIVOLI.

[61248.]—**Electrotyping.**—This query is not sufficiently definite. Is it required to deposit the copper as an adherent to the gelatine, or as a mask to be lifted off, as would be understood by the term electrotyping? The latter can be done by carefully plumbagoing the gelatine mould, and taking care that the surface is brought into metallic contact with the wire from the battery.—A. W.

[61255.]—**Embrocation.**—Mr. Shakespear will do more good by studying diet, than by any embrocation he can rub over his body at the seat of the liver. A good embrocation useful for many purposes is made by taking 1 drachm of oil of mustard, 40 grains of ethereal extract of mezereon, 2 drachms of camphor, 5 drachms of castor-oil, and 32 drachms of rectified spirit, mixing all together. If Mr. Shakespear will take advice, he should consult a medical man, and endeavour to forget that he has a liver.—NUN. DOR.

[61258.]—**Organ Couplers.**—If this querist will refer to No. 953, p. 391, he will find there an illustration of couplers applied to three manuals and pedals, which should give him all the information he wants. See also No. 547, p. 17. The coupling action has been illustrated many times in early volumes; but "W. W.'s" best plan would be to get a sight of one as actually arranged, before starting with the work.—ORGANON.

[61267.]—**Iron Poles.**—"C. F." omits an important part of his question, for though he gives dimensions of the tube poles, he says not a word as to the thickness of the iron in the "T's." However, if the weight of metal is equal, the "circular tube" poles will be stronger than those built up of T-iron bolted back to back.—NUN. DOR.

[61269.]—**Gramme Dynamo.**—I thought these questions had been answered almost to exhaustion. I should think the querist might be referred to back volumes.—J. T.

[61272.] — **Trains on Greenwich Line.** — Assuming the statements made to be facts, what more is to be said than that the line is so worked for sufficient reasons, which an observant traveller will discover at the terminal end?—E. G. P.

[61288.]—**Carmine.** — Thanks, "Cato." The recipe given is an old one, published many years ago in the "Encyclopédie Roret" (Fabricant des Couleurs). But "Cato" has been more fortunate than I. I have carefully repeated the process, and the result is absolute failure—a small quantity of precipitate of the colour and brilliancy of brick-dust, the greater part of the colouring matter remaining dissolved in the supernatant liquor.—P. O. V.

[61332.]—**Speeding Millstones.**—In my reply I took revs. of wheel as 10 per minute; but notice it is given as 5 only, so that in the case I suppose I should use 12 to 1, and then 2 to 1; or 8 to 1 and 3 to 1, according to size of water-wheel. But, as you are obliged to adopt the vertical spindle, and stones arranged around the central spur, this almost decides the case; but do not have the pinions on the spindles less than 20in. diameter, or the toes are apt to heat. This would only necessitate 3 to 1 on first motion—in fact, your present arrangement, under the circumstances, seems to me satisfactory.—T. C., Bristol.

[61349.]—**Spinning Metal.**—This art requires a good deal of practice; but it is rather surprising that it is not taken up by amateurs more than it is, for there is very little in it but practice! There is an illustrated article on the subject in No. 880, p. 513, to which the querist might refer for information.—SAML. RAY.

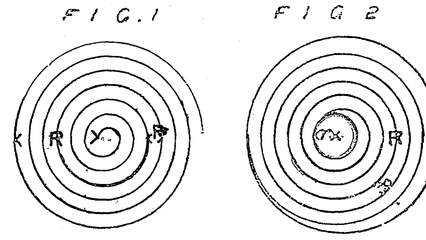
[61351.] — **Dip for Ironwork.** — Brunswick black will be the best to use for this purpose. This will dry in from one to two hours, and may be purchased from most oil and colourmen. He can make a good varnish himself, but will take much longer to dry. Boil a quantity of gas-tar for four or five hours, then add one quart of turpentine to every gallon of tar, and boil again for half an hour, care being taken that it does not boil over. Apply the varnish whilst hot.—G. G.

[61397.]—**Disposal of House Sewage.**—If "A. B." has a few square yards of garden, he will find the cabbage tribe to be greedy of all and every kind of sewage to an extent practically unlimited. A heap of the ashes, cinders, dust, &c., would effectually deodorise all house sewage; and when applied on his garden, the ammonia condensed in the cinders would be available ready to be greedily seized upon by his cabbage and other plant-rootlets. However, if the soil upon which his house is built be porous, then a cesspool would accommodate him. There is one other alternative: Get an empty cask or box, knock out the top and bottom, fix two handles on the sides, fill it (by a little at a time) with crushed coke or coarse cinders, pour on sewage, which will become filtered and deodorised. Renew the coke now and then, and sell it for manure to, say—THE DISPENSER (the Free Dispensary and Botanical Gardens, Lydney).

[61353.]—**Spiral.**—The following formulas will give the length of spiral:—

Let L = the length of a spiral
R r = radius
N = number of coils
P = pitch
π = 3·14

FIG. 1 FIG 2

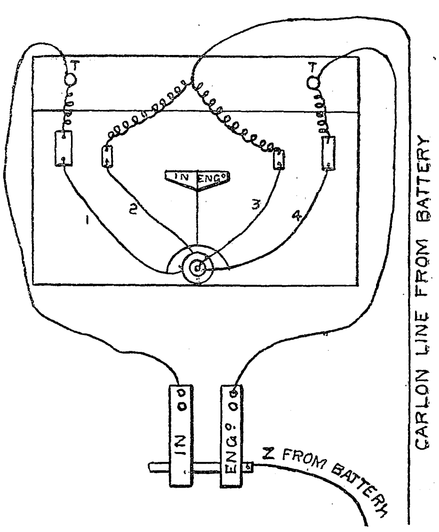


$$\text{Fig. 1} \begin{cases} L = \pi R N = \frac{\pi R^2}{P} \\ N = \frac{L}{\pi R} = \frac{R}{P} \end{cases}$$

$$\text{Fig. 2} \begin{cases} L = \pi N (R + r) \\ L = \frac{\pi}{P} (R^2 - r^2) \end{cases}$$

—JACOB GEORGE.

[61393.]—**Electric Indicator.**—"J. B." must bear in mind the bobbin is divided in two, the top being a little smaller than the bottom, and, of course, finer wire on the smallest part of bobbin. Wires: No. 1 is outer end of bottom part of bobbin;



No. 2 inner end of bobbin; No. 3 outer end of top part of bobbin; No. 4 inner end of bobbin; you will observe the action is by reversion of current through the bobbin; the wires being wound reverse. The sketch explains other connections.—E. SHEARER.

[61400.]—**Electric Light.**—This query seems to me to resolve itself into the following calculation: (Values used, 1H.P. = 33,000ft.-lb.; 1H.P. = 746 watts.) 1,500 tons of water per day of 12 hours; ∴ $\frac{1,500}{720} = 2\frac{1}{12}$ tons of water per minute = 4,666lb., and 4,666 × 40 = 186,640ft.-lb. energy of water fall. Efficiency of turbine wheel, 70 per cent. Therefore, 186,640 × $\frac{7}{10}$ = 130,648ft.-lb. = absolute energy conveyed to dynamo.

$$\frac{130,648}{33,000} = 3 \cdot 9, \text{ say } 3\tfrac{1}{2}\text{H.P.}$$

1H.P. = 746 watts. ∴ 3½H.P. = 2,611 watts.

Less by loss in dynamo, leads, and cables, 30 per cent. .... = 782 watts.

1,829

Efficiency of incandescent lamps is about 3 watts per c.p.; efficiency of arc lamps is about ½ watt per c.p. So that the dynamo would be capable of lighting 30 lamps, each taking 60 watts. But the number will vary inversely as their distance from the mains.—H. B. EDWARDS.

[61405.]—**Liquid Fuel.**—Redtenbecher gives the following equation for estimating the thermal value in heat units of any given fuel:—

$$W = 34500 \left(H - \frac{O}{8} \right) + 7050\ C$$

in which C, the carbon
H, the hydrogen, and } pro 1 kilogramme of the fuel.
O, the oxygen

Thus, taking as an example coal containing 78 per cent. of carbon, 5 per cent. of hydrogen, or 8 per cent of oxygen:—

$$W = 34500 \left(0{\cdot}05\ \frac{0{\cdot}08}{8} \right) + 7050 \cdot 0{\cdot}78 = 6879 \text{ heat}$$

units.—MARIENBERG.

[61432.]—**Voyage to Australia.**—A good supply of ordinary winter and summer clothing is all that is necessary, with topcoat and warm rug. Coldest weather likely to be met with equals moderate winter weather here, and hottest (at sea) little warmer than our hottest summer days—84° at the Line everywhere, and in the Red sea perhaps 90° or so. For hottest weather, a single flannel shirt, with summer jacket that buttons down (say, serge), and no vest is the best arrangement. Have come through the Red Sea 90°—94° in that way with the greatest comfort. Take old clothes for board ship and a decent summer suit for trips ashore, and you are well provided. A suit of flannel pyjamas make the best sleeping suit, and in hot weather is immensely convenient. Tennis shirts, with flannel collars, can always be washed. These should suffice for anything. Never wear cotton next skin. Two moderate sized portmanteaux are abundant accommodation for 12 months. They can both be kept in cabin as a rule, while a trunk has to go below. Avoid all fancy notions—linen suits, white umbrellas, revolvers, and sich. If on a sailing ship, a tin or two of water biscuits by way of private stores keep well and are always sweet. A pocket-flask of good brandy for emergencies is useful, though it may never be wanted.—H. P.

[61438.]—**Measuring Cloth.**—Are you not in error, "Milverton," in taking 12 as the first term of the series? I think it ought to be 12 plus the common difference, as the roller itself equals 12. This may seem a very small matter at first sight, but when wrought out for the different circumferences you tabulate in your reply it comes to be very considerable. By a little algebra we find the common difference to be $\frac{60}{199}$; then, by the common rules of arithmetical progression, we find, when—

C is 24 L = $722\frac{2}{5}$
C 30 L = $1262\frac{7}{10}$
C 36 L = $1922\frac{2}{5}$
C 48 L = 3600

differing, as you will see, by $9\frac{3}{5}$, $7\frac{4}{5}$, $5\frac{3}{5}$ respectively from the results of your working.—WORKMAN.

[61442.]—**Weight of Moist Air.**—Thanks to "Milverton"; but I do not see his reason for putting $V'' = V'$, or, rather, the bearing of this on the interpretation of the formula. The terms used in Watts's formula and mine have definite meanings; if these are the same in both cases, the formulæ cannot both be right. The formulæ differ in multiplying, or not, the wt. c.ft. vap." by $\frac{p - E}{p}$. I take "wt. c.ft. vap." to mean "wt. c.ft. sat. vap. at temp. t, and (necessarily) at the corresponding press. E." What meaning does Watts assign to make his formula right? Perhaps "Milverton" would kindly deal with the following, from Watts's table $p = 30$, $t = 100°$.

wt. c.ft. dry = 479·93gr.
wt. c.ft. sat. vap. = 19·84
wt. c.ft. moist = 486·65

Using E = 1·918 from another table in Watts, I do not get for moist 486·65 with either formula, but nearer to it with mine than with that said to be used in Watts.—L. S. A.

[61456.]—**Caustic Soda Process.**—An account of the torpedo boat *Peacemaker* appears on p. 82, this volume, in which it is distinctly stated that she is driven by steam generated by a caustic-potash boiler on Honigmann's plan, potash being better, I believe, than the soda. The principle of the Honigmann system will be found at p. 598 in No. 962, the No. for Aug. 31, 1883; but it has nothing to do with the query, except the title. The title of this query is misleading, for obviously what "C. L. S." wants to know about is the acetate of soda foot-warmer used on the L. and N.W.R., which was described in No. 785, p. 107, as having been tried on the Paris-Marseilles line. In No. 868 there are illustrations of the acetate of soda stove patented in this country by Herr Nieske, of Dresden; and in previous numbers there are more or less full descriptions of the invention of M. Ancelin, which is based upon the fact that solid bodies when passing into the liquid state absorb heat, which they give out when reverting to the solid state. Acetate of soda is a suitable material for the purpose. A foot-warmer of a capacity of about two and a half gallons will hold about 33lb. of acetate of soda, which melts at 139° Fahr. The loaded foot-warmer is, then, immersed in boiling water, which causes the acetate to melt, when it absorbs heat; and assuming its temperature when placed in a carriage to be about the same as an ordinary water-filled foot-warmer, it gives off about four times as much heat. Thus, in cooling to 140°, it gives off so many units, and then as it enters the solid state it yields up the heat which had been rendered latent; but the chief merit of acetate of soda is that it enters the solid state slowly, and the whole of the latent heat is not given up suddenly. Perhaps some of your railway readers can tell us how the system answers on the L. and N.W.R.—SAML. RAY.

[61458.]—**Circular Saw.** — The sizes I gave were for a separate saw bench. What I said was that "many tool-shops kept them in stock."—T. C., Bristol.

[61458.]—**Circular Saw.**—Don't put an 18in. saw on a lathe; small saws up to 8in. are very useful but 18in. will never do driven by power, say, between one and two thousand revolutions a minute. Here are a few reasons:—Lathe framing too shaky, saw table being above centres, too high to work at, and too convenient for a crack in the face by pieces flung from the saw; besides, a saw and spindle that weight would be a nuisance in shifting every time the lathe was wanted for turning, &c. Let Mr. Walter Payne get No. 11 this Vol., and on p. 231 he will find, in a first-class article, how to go to work to build a good, solid, separate frame, and do not be afraid of making it too strong.—ALBERT COLLINGRIDGE.

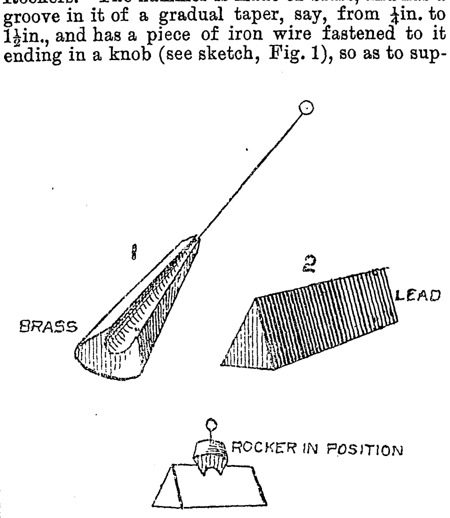
[61459.]—**Coils for Galvanometer.**—In last line but one of my reply, page 485, for "then make, &c.," read "these make."—OHM.

[61463.]—**Propulsion of Weight.**—Thanks to "Elag" and Mr. Conry for their replies; but the reference of the former to the balloon does not answer my question as to air, as a balloon is a mere inanimate bulk dependent for its motion on an outside current of air. I want to know what power a bird uses to propel its weight. Could he not also inform me as to the man and horse? I want to get at the power given out at the foot and hoof to move the weight of the body only.—W. G. G.

[61466.]—**Gold Gilding.**—Get some gold-size and mix a little chrome yellow with it; paint the article, and when nearly dry, but still a little sticky, gently brush your hair with a flat brush, and the brush will then pick up the gold leaf, which you can then lay on the work, and pat it down gently with a pad of cotton wool, when it ought to look like solid gold.—E. R. DALE, F.S.Sc.

[61470.]—**Legal.**—As to bulging out, much depends on the terms of the lease, and on the state of the building when tenancy commenced. As to defective roofing, leaseholder is without doubt liable.—G. J.

[61497.]—**Singing Hammers.**—I have never made one of these myself, but have seen one on the lecture-table. They are also known as Trevelyan's Rockers. The hammer is made of brass, and has a groove in it of a gradual taper, say, from ¼in. to 1½in., and has a piece of iron wire fastened to it ending in a knob (see sketch, Fig. 1), so as to support one end on the table. The piece it rocks on is not wood, but a △ of lead (Fig. 2). When the narrow part of the groove is placed on the lead a very sharp note is produced, and vice versâ. The sound will last for about 20 minutes. The inclosed rough sketches will give "S. H. W." some idea; but they are only from memory.—A. R.



[61472.]—**Damp Houses.**—The simplest form of hygrometer is a strip of carbon tissue, as recommended by W. B. Woodbury. In an atmosphere at all damp, the tissue becomes limp, and is a visible witness of the state of the air, and could be understood by the meanest capacity; in a dry atmosphere the tissue is quite hard and brittle, and curls up, pigment side inwards; if the air be very damp the tissue will curl up pigment side outwards.—G. J.

[61486.] — **Petroleum Gas - Engine for Launch.**—Before attempting to give "Glasgow" *reliable* advice regarding the most suitable form and proportions for a 40ft. steel launch intended to steam at not less than ten miles an hour, it would be necessary to know something of the purposes for which the craft is required—e.g., for pleasure or for heavy work. If "Glasgow" will advertise his address, I will be glad to assist him.—DUMBARTON.

[61499.]—**Storage.**—I am afraid that the only way to prevent the gas coming off is to discharge slower; gas given off is, as you say, energy lost, and occurs more or less at all times when using secondaries. When charging, you will see the same escape if you only charge fast enough; it is, however, more economical to both charge and discharge slowly; in fact, it is only by a moderate rate of charge and discharge that efficiency as claimed of 90 per cent. can be obtained; but when the batteries are charged and discharged at the rate stated by the makers, then the efficiency will rarely exceed 60 per cent.; however, the great convenience of this cell is worth some loss. It is quite true that a stranded conductor has more weight, and hence less resistance, than the same number of wires unstranded. This is simply owing to the fact that in stranding, the wires going round each other like the strands of a rope, become shorter, and the quicker the lay, or the greater number of twists per foot, the less the resistance. You can easily satisfy yourself upon this point by cutting a few 6ft. lengths of wire and twist them up together, when on completion you will find they are considerably under 6ft. Incandescent lamp bulbs are silvered by the same process as the silver-on-glass mirrors are done, and full details are given in back numbers.—OHM.

[61503.] — **Radial Axles.** — Yes, the Great Northern 7ft. 6in. new engines and the 715 class have radial boxes, or they could not get round curves.—LOCO.

[61504.]—**Double Electric Bells.**—A full-stop should be placed after "moment," 6th line from bottom; and the 5th line should read "For telegraphic purposes though." Altering the punctuation (as it now appears) makes the last six lines contradict the former.—M.M.I.SC.S.

[61505.]—**Eyepiece for 3⅛in. Telescope.**—I should advise "Enquiry" to procure his three eyepieces of the following powers: 65 for clusters and nebulæ, 120 for planetary and general work, and one of 200 to 250 for double stars. The o.g. is certainly all the better for being of long focus, a larger image being formed.—H. A.

[61505.]—**Eyepiece for Telescope.**—If "Enquiry's" 3⅛in. be achromatic, he might provide it with astro. powers of 50, 100, and 200, which would be pleasant to use and not too much for the object-glass to bear. The focal length he mentions is no drawback—rather the reverse, as it takes some of the strain of magnification off the eyepiece. He will, of course, mention it to his optician in ordering the lenses.—ARTHUR MEE.

[61507.]—**C ondensing Benzoline.**—It cannot, as a liquid, be compressed to any extent sufficient to make it worth while doing. You could freeze it, but that would be no use for carrying about, except, perhaps, on an Arctic expedition, and then artificial freezing would be needless. As to compression, the very act of compression generates heat.—EDWARD CONRY.

[61508.]—**German Root Words.**—J. Shippam, if he understands French and does not object to the use of a book beyond his dictionary, will find what he contemplates doing already done in a small work — viz., "Vocabulaire Allemande-Français Etymologique," by J. A. Weiss-Haas, published at Geneva, by H. Georg, which he can obtain for about 2s. 6d. from any foreign bookseller in London.—EYE-WITNESS.

[61510.]—**Roller Covering.**—You might try Prout's cement, procurable in Broad-street, Golden-square, and elsewhere. I think it is guttapercha and pitch mixed. It is sold in penny sticks, applied with heat, something like sealing-wax. The best cement I have found for leather is Le Page's carriage glue, procurable at Richards, Terry, and Co., 46, Holborn-viaduct, and nearly all tool shops, &c.—T. F. S. T.

[61510.]—**Roller Covering.** — Do not quite understand what you mean by "fastening cloth on iron rollers and under leather." The following will, however, piece leather. Bisulphide of carbon 4oz.; indiarubber, in shreds, 1oz; isinglass two drachms; guttapercha ½oz.; dissolve the whole lot in the bisulphide of carbon. Apply a thin layer

to each of the two pieces required to be united, and let it dry. Then heat to melting, place the parts together and hammer the air bubbles out. Le Page's liquid glue is a capital thing for the same purpose.—W. HOLDER, Newport, Mon.

[61511.]—**Dynamo.**—A dynamo giving 6 ampères at 45 volts would probably light well six 20c.p. lamps of about 48 to 50 ohms cold resistance. A gas-engine of about ½H.P. would do the work if the dynamo is well made. I cannot, owing to my natural modesty, reply to the question about the best lamps; the Otto or the Atkinson engines are the best and cheapest in the long run. A heavy flywheel on dynamo steadies it.—S. BOTTONE.

[61511.]—**Dynamo.**—If this querist could speed up his dynamo a little, he could light five 20c.p. 50-volt lamps, each absorbing 1·3 ampère, and having a resistance of 38 ohms. Otherwise he must use 45-volt lamps 45 ohms resistance and absorbing one ampère each, arranged in parallel arc, and probably 16c p. If a gas-engine is the motive power, a flywheel on the dynamo-shaft is almost a necessity, especially if the engine is not well up to its work. Employ an engine of ¾, or preferably 1H.P. indicated.—J. H. H., Edenfield.

[61512.]—**Magic Lantern.**—The kaleidoscope would have to have the revolving part fixed so as to come into the same position as an ordinary lantern-slide. Then a lens will be required of an equivalent focus to the length of the kaleidoscope tube to be placed at the end instead of the front lens of the lantern.—JAMES W. GARBUTT, Leeds.

[61513.]—**Incandescent Lighting.**—To MR. BOTTONE.—There need be no change of wire on field magnets; of course, the E.M.F. of the machine will be less, say, equal to four, or at most five, 20c.p. lamps. I should almost advise you to wind the F.M.'s as a shunt machine, and put on about 8lb. of No. 20 (2lb. on each limb, connected all up in series), and then attach the ends of the F.M. wires to the brushes. See No. 1113, Vol. XLIII. p. 466.—S. BOTTONE.

[61514.]—**Lining for Accumulators.**—I can tell you what you want; but the description would be too long for publication, as more lies in the peculiar application of the substance than in the substance itself. If you like to write to me I will explain further; you will get my address from the proper column.—EDWARD CONRY.

[61514.]—**Lining for Accumulators.**—An acid-proof cement may be made by dissolving caoutchouc by carefully heating it in twice its weight of linseed oil, and then adding twice its weight of pipeclay. This composition, when heated, becomes softer, but does not melt, and can be kept for a long time in a damp place without hardening, and when it does get hard it can be softened again by oil of turpentine. The last few remarks refer to a mass of the substance, and not to a thin layer. The following is a heat and acid-proof cement: Sulphur, 100; tallow, 2; resin, 2. Melt these together to a ruddy syrup, and add sifted ground glass to form a paste, and heat when used. Marine glue might also suit your purpose.—W. HOLDER, Newport, Mon.

[61515.]—**Photographs.**—To R. A. R. BENNETT OR OTHERS.—I think something must be wrong with this besides over-development, unless you have got the image reversed in some way, which does not often happen. If the negative is too dense, it will have to be reduced with chloride of iron, or something similar. If it really is turned into a good positive, the shortest way would be to take a negative from it by contact.—R. A. R. BENNETT.

[61516.]—**Gramme Dynamo.**—This machine, if query be correctly understood, will certainly not present a very compact appearance with "yokes" 18in. long. Taking into consideration the diameter of the armature, the length of these might have advantageously been decreased one-third. One good point is in the single pair of field magnets, which are preferable to the double pair as described in the 30-lighter. The armature will take about 6lb. of No. 18, giving a running res. of ·88 ohms. The field magnets for incandescent lighting should be wound as a shunt. The machine will probably light eight 20c.p. lamps, at an E.M.F. of 50 volts, and absorbing 1·3 ampère each, with a resistance of 38 ohms. These arranged in parallel would present a res. of 4·75 ohms, so that the total external res., allowing for leads, &c., may be taken at 6 ohms. This resistance, squared, and divided by the res. of A, will give res. of shunt coils = 40 ohms, or, say, 20lb. of No. 20. If this quantity does not sufficiently excite the field magnets, querist might add 5lb. No. 16 on each F.M. in series. The speed will be about 1,500, and should be regulated to give just 50 volts current, 11 or 12 ampères. Employ a 1½H.P. engine. There is no fear of heating unless the machine is overloaded, or the terminals short-circuited.—J. H. H., Edenfield.

[61518.]—**Gas-Engine.**—The two statements are very much conflicting, and if you have accurately quoted the latter one, I should advise you to throw that book overboard. The cooler the cylinders of a gas-engine can be kept the better; it is even cheaper to pay an increased water-bill, in order to keep a constant circulation of cold water round the outside of the cylinder, than to let the latter run hot; the mischief of over-hot cylinders is not merely that of loss of power: it is a continual risk of the engine straining itself, especially a gas-engine, these being more lightly built than steam-engines, and a strained engine is like a strained back—half crippled for ever after.—EDWARD CONRY.

[61519.]—**Lead Cylinder.**—Take a belt 1in. wide, section = 1in. × ½in. = ½ square inch. Tensile strength of lead = 1,792lb. ∴ ½ square inch = 896lb. Half diameter = 9in. × width of belt 1in. = 9 square inches. $\therefore \frac{896}{9}$ = 99·5lb. per sq. in. = bursting pressure.—ELAG.

[61519.]—**Lead Cylinder.**—Taking this as being cast, and of a tensile strength of 1,790lb. per square inch., the bursting pressure = 1,790 ÷ 18 = 100lb. per square inch nearly; but this assumes the cylinder kept its form until it ruptured, which it would not, and 60lb. is nearer the mark.—T. C., Bristol.

[61520.]—**Brass.**—There must have been some defect in the fittings of the thermometer. I have had one in constant use for more than ten years in an exposed situation, and the fittings appear as good as ever. If "G. M. S." lives in a very smoky neighbourhood, his brasswork will have been affected by the action of sulphur.—H. A.

[61520.]—**Brass.**—The plain English of the thermometer business is that the fittings were not "brass" at all, but some vile compound of scrap metal and odds and ends which had been thought good enough for thermometer fittings on account of there being no mechanical strain upon such. Good brass will stand any amount of exposure, even to sudden changes of temperature; as a matter of fact, brass is much less affected than iron or steel by a sharp frost. Good brass fittings, however, are only to be found in apparatus bought from good makers at good prices. Most of the "brasswork" sold nowadays is a nondescript alloy that even the makers could not particularise.—EDWARD CONRY.

[61520.]—**Brass.**—I don't think the optician that "G. M. S." went to knows much about brass; if he does, will he be good enough to explain how it is that brass door handles, door-bell handles, door plates, dog collars, &c., to say nothing of firemen's and soldiers' helmets, buttons, &c., do not fall to pieces when they are being cleaned a "few days" after purchase. I have seen brass all thicknesses cleaned the proper way every day, or every week, for many years; but I have never seen it fall to pieces as stated by "G. M. S." I have always found the cleaner you keep brass the better it will resist the atmosphere. The brasswork on "G. M. S.'s" thermometer must have been neglected to be cleaned a good many times before he had it, or the brasswork has been brightened with nitric acid, or some other acid, and the acid not properly cleaned off after—in that case, the brass would soon perish and fall to pieces.—DUNCAN.

[61521.]—**Does Iron Fossilise?**—It is quite possible that iron should fossilise; but it is more probable that the fossil is that of an encrinite, or other marine growth, coral, shell, &c.—M. YORK.

[61521.]—**Does Iron Fossilise?**—No. Iron is an element which you may disperse or adulterate, but cannot change; iron will, however, become coated first with rust, and over the rust with calcareous deposits, giving it the outward appearance of a pure fossil.—EDWARD CONRY.

[61522.]—**Questions as to Evolution.**—Last year two papers appeared almost simultaneously, one in German, by De Graaf, and the other by Baldwin Spencer, of Oxford, on the "Pineal Gland." Both worked independently and in different animals, and both arrived at the conclusion that the gland represented a rudimentary eye, comparable with that of amphioxus, and was apparently of an invertebrate character. The pineal gland is best developed in "Hatteria." In this animal the optic vesicle of the pineal eye consists of a lens and retina, both of which are derived, apparently, directly from the brain, thus differing from the paired eye of vertebrates, where the lens takes its origin as a secondary invagination of the epiblast, and from the invertebrate lens, which is epidermal in its origin. The retina shows decided invertebrate characters; the rods bound the cavity of the optic vesicle internally, and the nerve enters it posteriorly, and the nervous elements generally are directed towards the light. The eye is connected by a solid stalk with the "epiphysis," which is merely an enlargement of the optic nerve of the pineal eye. In no living amphibian does the pineal gland develop into an eye; but it did possibly so develop in the extinct Labyrinthodonta. In Pisces it is merely a hollow outgrowth of the brain, and in Mammalia and Aves it has become much degenerated. I have a diagram of the pineal eye of Hatteria punctata at hand, and would be glad to send it to "E. M." if it would be of assistance.—L. B. AND S. C. R.

[61523.]—**Bell Circuit.**—The earth can be used for return wire in an electric-bell circuit, and will be quite as efficient as running another return wire. If you have gas or water laid on to your premises, or where you want to put up the bell, connect one pole of the battery to the gas or water pipe at one end, and one wire from the bell to gas or water pipe at the other. If you have no gas or water, you will find full instructions in No. 1138 "E. M." in the Reply Column.—JOHN THOS. GARBUTT.

[61523.]—**Bell Circuit.**—Yes; earth can be used efficiently as a return circuit for an electric bell, provided your battery is sufficiently strong and you make a good earth connection, which can very easily be done by soldering your wire to a pump pipe or to a thin sheet of copper or lead (say 1ft. by 3ft.) and burying it about 3ft. under ground in a good moist place. If you surround plate with coke, it will improve the connection, and an occasional bucket of water won't hurt it if it should happen to be upset somewhere about there.—W. HOLDER, Newport, Mon.

[61523.]—**Bell Circuit.**—"Earth" makes an admirable return for a bell circuit. To make a good earth take two short wires down to earth, one at each end of the stretch—the first one from the zinc of the battery, the other from the bell—solder each wire well to a copper plate about 1ft. square and any thickness, and bury your plates in the earth not less than 4ft. down. Or strip and scrape or polish with emery paper three or four yards of each short earth wire, and dig a small trench at, say, 4ft. depth, put a bushel of coke (broken up small) into each and bury the wire in the coke, winding it in and out like a serpent; drench the coke well with water and fill up with earth, beating the earth next to the coke down upon it so as to consolidate it. Or solder each short earth wire to a waterpipe. Or drive two lengths of gas-barrel about 4ft. down into the earth, and solder the wires firmly to the respective ends. Galvanised iron pipe is better still.—EDWARD CONRY.

[61526.]—**Wheel Barometer.**—The spindle of the large pointer is attached to a pulley at the back of the instrument; on this pulley is a silk thread, at one end of which is fastened a glass float resting on the mercury, on the other a counter-weight. It is very likely this thread has got on to a wrong groove in the pulley. I should strongly advise "T. G." to take his barometer to some practical instrument-maker to be put right.—H. A.

[61526.]—**Wheel Barometer.**—To make your instrument read correctly, either take out a little mercury or move the hand round upon the spindle. To reconnect the brass pointer, take out the wood back and then take out the tube, when you will see the long brass plate tacked on to the barometer. Take this out, and at the other side of it you will find two small pulleys, which, if the barometer is in working order, will be connected by a small band, made of silk or cotton. In your instrument I think this must either be too slack or broken altogether. Either make a new band, or shorten the old one. You will have to take both hands off before you can take brass plate off. If you get firm hold of the small double-grooved pulley at the back of baro. with a pair of ordinary pliers, and then take hold of the hand at the front, I think you will find it will come away.—JOHN THOS. GARBUTT.

[61527.]—**The Agar-Agar Cell.**—The only description I can find of this cell is the following, which I take from the *Electrical Review* of June 18th, 1886. It originally appeared in *Engineering*, on June 11th. "The cell consists of a flat glazed earthenware tray, containing a sheet of silver foil on its floor. Dry powdered chloride of silver is spread over this plate, and a vegetable jelly is laid over that to support the zinc plate, which is the upper pole of the cell. This jelly is made by dissolving ammonium chloride (2½ per cent. of the salt) in Ceylon Moss or Agar-Agar. A pile of these cells makes a convenient battery.—W. HOLDER, Newport, Mon.

[61528.]—**Seeds for Microscopic Objects.**—Speaking generally, the seeds—or, more correctly, the fruit—of the umbelliferæ are by far the most interesting for the microscope, on account of the varying number and shape of the ridges and channels, and the oil receptacles, or vittæ, in the substance of the pericarp. Nearly all the English genera have vittæ, Conium being the most notable exception. You may try Coriander, Parsley, Fool's Parsley (Æthusa cynapium), Hemlock, Anise (Pimpinella anisum—not the star anise), Parsnip, and Celery. Pepper, cloves, and coffee also make good objects.—REYMOND.

[61528.]—**Seeds for Microscopic Objects.**—If "Lavant" will procure any of the seeds

named in the following list, he will find they possess beautiful and peculiar markings; they all belong to the wild species. I simply give common names. If "Lavant" requires the scientific names, and will advertise his address, I shall be pleased to furnish the same, also orders to which they belong. Hound's Tongue, Wild Carrot, White Campion, Red Campion, Ragged Robin, Ground Pine, Common Mallow, Bur Marigolds, Sundew, all the Poppies, Foxglove, all the Orchids, all the Geraniums, Mullein, Bog Asphodel, and, in fact, they would all repay the trouble of hunting up; all, except the Asphodel, Sundew, and Orchids should be mounted dry opaque.—WORKING-MAN BOTANIST.

[61528.]—**Seeds for Microscopic Objects.**—Beginning with the seeds of Collinsia, which, if the testa be cut and placed in water, will begin to throw out fibrils which seem to be alive, and the movable elaters of the Equisetum spores, we have the following striking and interesting seeds, some of which may be viewed with a low power, say, 1in.:—Stellaria holostea and media, Lychnis dioica and diurna, Dianthus barbatus, Papaver somniferum, Spergula arvensis, Eccremocarpus scaber, Coreopsis tinctoria, Wahlenbergia hederacea, Eschscholtzia Californica and tenuifolia, Portulacca oleracea, Lepigonum marinum, Silene inflata, Euphorbia Greca, Plantago psyllium, Loasa aurantiaca, Antirrhinum majus, Nicotiana tabacum, Sphœnogyne speciosa, Bœhmeria nivea, Linaria minor, Centaurea cyanus, Nycterinia capensis, Lophospermum scandens, Erica cinerea, Euphrasia officinalis, Calluna vulgaris, Antirrhinum orontium, Eutoca viscida and multiflora, Whitlavia grandiflora, Verbena pulchella, Pedicularis palustris, Digitalis purpurea, Isotoma longiflora, Anagallis indica, Eucharidin concinnum, Oxalis rosea and acetosella, Campanula speculum, Apium graveolens, Blumenbachia insignis, Ulmus montana. See "Cooke's 1,000 Objects for the Microscope."—S. BOTTONE.

[61529.]—**Mathematical—Measurement of Drums.**—Take 1ft. for the unit of measure. Let l be the length of the rope, t the thickness of the rope, h the length of the barrel of the drum, d the diameter of the barrel, and e the diameter of the end of the drum. Then the number of layers of rope required to fill the drum is $\frac{e-d}{2t}$, and the number of turns in each layer is $\frac{h}{t}$. Adding together the lengths of rope in each layer, we have, for the whole length of rope, the following series:—

$$l = \frac{\pi h}{t}\left\{d + \overline{d + 2t} + \overline{d + 4t} + \&c. \ldots\ldots\ldots\ldots + d + \left(\frac{e-d}{2t} - 1\right) t\right\} = \frac{\pi h}{4t}(e-d)(e+d-2t).$$

From this we derive—

$$e = t + \sqrt{(d-t)^2 + \frac{4t^2 l}{\pi h}} \ldots\ldots\ldots\ldots \quad (1)$$

$$h = \frac{4t^2 l}{\pi(e-d)(e+d-2t)} \ldots\ldots\ldots\ldots \quad (2)$$

in which expressions $\pi = 3{\cdot}1416$.—J. R. CAMPBELL, Charing, Kent.

[61531.]—**Lantern Transparencies.**—The only way is to fix up the ½-plate negative in front of a camera with a reflector, say of white paper, at an angle of 45° at the back of it, and take a positive in the camera of the required size. All light must be shut out between the negative and the camera. —G. J.

[61531.]—**Lantern Transparencies.**—The best way is to make the transparencies in the camera. I do all my lantern-slide work by wet collodion, and so make all slides in the camera from ¼ upwards. Get an extra bellows made to fix on front of your ordinary camera, which should be clear through, and say 24in. long, the diameter at the end farthest from the camera, say, 9in. by 9in., so as to take a carrier for a ¼ either way up; have a foot made to the end and clamp both camera and extra bellows to a long board. You will find that you require very long exposures with the ordinary chloride plates.—JAMES W. GARBUTT, Leeds.

[61531.]—**Lantern Transparencies.**—Get an old box about a foot square, and take off the lid, cut a hole in the bottom slightly smaller than the negative you desire to reduce, fasten the negative outside this hole, film side inwards, lay the box on its back. Nail a board so as to increase the height of where was formerly the back of the box. On this screw the camera at such distance as is found necessary with the lens pointing to the negative. Put the lantern slide plate in a carrier in the camera back, having previously focussed, and expose. To get even illumination, tilt the apparatus so that nothing can be seen on looking through the negative but sky, or reflected light through the negative by a looking-glass or sheet of white paper. The inside of the box should be blackened, and during exposure everything should be covered with a black cloth except the side of the box where the negative is, that no light may pass through the lens except that which has come through the negative. The plates should be fairly rapid ones (I find Chapman's lantern plates answer well), and a short-focus lens is more handy than a long-focus one. I use a 4in. portable symmetrical.—T. PERKINS Shaftesbury.

[61533.]—**Speed Wheels.**—Will "A Country Millwright" buy the MS. of the book, and himself undertake the responsibility of the "ready demand?"—M. YORK.

[61533.]—**Speed Wheels.**—I beg to second this request for a book of speed wheels. At present there is only a very small one, which has a very poor selection. But I should also suggest that it contain "A complete division table from 12 to 200, the result expressed in decimals, which, multiplied by pitch of lathe-screw, would give pitch required." Also a few complete sets of numbers for division plates, showing exactly what each primary can be reduced to. I have been obliged to make a small book for private use, simply to save frequent calculations and time.—VULCANITE.

[61534.]—**Lathe Tools.**—I expect you burnt the steel in heating. It should never be heated beyond "cherry red."—EDWARD CONRY.

[61537.]—**Bleaching Silver.**—Boil the articles in cyanide of potassium till the frosting comes up clear and white; then wash in very hot water, using a stiff brush with a touch of soap and carbonate of soda, and dry off by shaking in a bag of hot boxwood sawdust. Boiling in a solution of alum will answer for some articles, but it takes a longer time, and is hardly so effectual as the cyanide.—DENS.

[61537.]—**Bleaching Silver.**—The cyanide of potassium is used for gold lace, and I think, for silver also. The lace is merely dipped into a mixture of the cyanide with water, more or less strong according to the state of the lace; half and half is a general mixture. The time of dipping is very short, and depends on how much the lace is tarnished; often a single second is enough. The lace is then rinsed well in clean water and left to dry.—EDWARD CONRY.

[61537.]—**Bleaching Silver.**—To one half-pint of water add thirty drops of oil of vitriol. Smoke the article to be bleached over the gas until it is black, then place it on a piece of charcoal, and heat the article until the smoke disappears—that will be when the article is about red hot; when cold, place it in the above solution from fifteen to thirty minutes, then place it in clean hot water. If you want to burnish parts, dry at once in boxwood sawdust, then burnish; if to be finished with the scratchbrush, dip in hot water, scratchbrush, and dry in box dust. There is lots of silver jewellery that would not be safe to bleach for many reasons; but, above all, be careful and see that there is no pewter solder about the article. It would take too much space to explain other reasons; but if you are in doubt about any article, apply again, or publish your address, and I will help you. —DUNCAN.

[61541.]—**Polish.**—You should have used spirit to it.—EDWARD CONRY.

[61542.]—**Clock and Sundial.**—Think the matter carefully over again, and try to reason it out. You will, I fancy, find Lockyer to be right. —H. A.

[61542.]—**Clock and Sun Dial.**—The quotation implies that at January 1 the sun is gaining most on the clock, which is true; but it is only very slightly before the clock; but at July 1, when it is "in apogee," and moving slowest eastward, in reference to the stars, therefore "fastest" westward per hour, in reference to the dial, it is also gaining on the clock, and quicker than it ever loses; for the days in spring and autumn, wherein it is losing, are about twice as many as those in summer and winter, wherein it gains. The whole quotation is certainly very faulty.—E. L. G.

[61544.]—**Darning Machine.**—These were returned by some of the sewing-maching shops as unsatisfactory, and as needing further development before they were likely to come into good use. And there is a splendid opening for some inventor who will supply a really efficient darning machine. To work it, my recollection is that you raise the clamp, put the part needing darning over it, press the clamp down, which presses the material into corrugated ridges; then force the needles through till all the eyes project through the work; then pass the thin hook (supplied with the machine) through all the needles, hook the worsted, and draw it back through all the eyes, hold on to the end, and draw from between each needle enough worsted to hook over one tooth of the many tongued forks. When all is threaded, draw back the needles, which draws the double threads through the stuff; cut off all the ends, lift the clamp, turn the material at right angles to its former position, clamp it, and go through the operation as before, when the darn will be finished. The only thing I am not quite sure about is whether the needles have to be threaded before the work is put into the clamp. It was in the Centennial Exhibition in 1876 I tried the machine, so I may be excused if I have forgotten the exact process. Will "F. C. A." return the compliment now, and let me know where I could pick up one of these machines? I have not seen one for many years.—T. F. S. T.

[61545.]—**Railway Couplings.**—An ordinary screw coupling should not break with less than a strain of 25 tons.—ENGINEER.

[61546.]—**Harmonium.**—Mr. Begg cannot easily add a half-set to his present harmonium, for he will require a new pan, which, being wider than the present, cannot well be got into the case.—ORGANON.

[61546.]—**Harmonium.**—The addition of a half-set of reeds would certainly be an improvement to your instrument in one respect; but it is well to consider the matter sufficiently before commencing the desired alteration. If your harmonium contains a good and sound 10in. bellows, you can make it do; but you will require a new pan, arranged in three registers, so as to receive a row and a half of reeds. Buy a good pan, with beech veneers, from a good maker, and don't forget to pay a reasonable price for it. A cheap or inferior pan or soundboard is a curse to any harmonium. A good tone depends largely on the quality of the soundboard. Buy Turban's or Esteve's best reeds. You will also require a valve-board, arranged for three registers, and furnished with three valves actuated by the stops. You can introduce the following stops:—Cor Anglais (bass), Flute (treble), Voix Celeste (additional half-set of reeds). You can have them to sound celeste without having the reeds put out of tune to the flute set. I will explain how to accomplish this, if required. By all means have the expression stop. This stop merely consists of a valve placed at the bottom of well underneath the valve-board, and which covers the hole through which the wind enters the reservoir of bellows. When the expression-stop is drawn out, the valve closes, and prevents the air from entering the reservoir. If I may be allowed to express my candid opinion with regard to the matter, I do not advocate or advise anyone to make any addition with regard to number of reeds to any instrument (more particularly one-row reed organs) unless there is ample space in the instrument for doing so. Where space is very limited, and the mechanical portions are cramped for want of room, satisfactory results can scarcely be expected.—G. FRYER.

[61547.]—**G. and S.W. Locos.**—The G. and S.W. engines are very fine, and do good work with the joint stock traffic. They have one fault: they require domes, so as to get the steam more dry to the cylinders.—LOCOMOTIVE.

[61547.]—**G. and S.W.Ry. Locos.**—In reply to "G. and S.W.Ry. Fitter," although I have never had very much travelling to do on this line, my experience of these 6ft. 9in. four-coupled and the 6ft. bogie express engines has been very satisfactory. They have always kept excellent time, notwithstanding heavy trains, bad weather, &c. Their coal bill, I believe, is not at all heavy, the trains and gradients being taken into consideration. There is one detail of construction which I do not so much admire—that is, the absence of a dome. I suppose that these engines are liable to prime if they have a full boiler at starting; it is well known that the G.N.R. cannot carry a full boiler, which is really perhaps the only bad point in them. Does the joint of the steam-pipe with smoke-box give any trouble, as it is under steam at all times? The reversing gear I consider particularly ingenious, but if anything was to go wrong with the steam connections the engine could not be reversed or even notched up to suit the gradient. I am glad that Mr. Smellie keeps to the link motion, notwithstanding the disadvantages of short axle bearings, which cannot be avoided when the slide valves are between big cylinders, as 18¼in. I hope that no more new engines will be fitted with the Bryce-Douglas gear; it has had a fair trial, and to all accounts has not acquitted itself satisfactorily. —G. T. G.

[61548.]—**Shipbuilding.**—"Novice" should say what sized ship he means, and the material of which it is made. If only a small one, say, 4ft. long, a gimlet will suffice, and it is easy to carry the vessel to the water. Is his query intended to be funny?—VIDEO.

[61549.]—**Coil.**—It is a settled fact that silk-covered wire is better for the secondary coils of inductoriums than cotton-covered. This depends on two reasons: 1. Superior insulation of silk-covered. 2. Because the insulating covering in the case of silk occupies very much less space, hence the coils lie nearer to the core, and to each other. This greatly enhances the effect. Yes; but a paper tube soaked in paraffin wax is decidedly better.—S. BOTTONE.

[61549.]—**Coil.**—Not at all. Cotton-covered wire will do perfectly well; only cotton insulation taking up more room than silk, you cannot get as many layers of cotton-covered wire into a space as you can of silk, and consequently, size for size, you cannot get as good results with cotton-covered coils as with silk-covered. With small coils it costs almost as much in extra cotton-covered wire to get the same result as it would have done to use silk-covered, and the latter insulation is always much better than the former. I would as soon have one covering of silk as two of cotton for insulation. I expect the No. 40c.c. was for making what is called "net" for bonnetmakers. I hardly understand your last question. It is absolutely certain that you cannot make an "ebonite tube" out of "a piece of sheet iron," unless you are a necromancer of high ability.—EDWARD CONRY.

[61549.]—**Coil.**—Fine wire covered with cotton used as a secondary in spark coils will only result in a disappointment. The tension between the layers of secondary is great, and the cotton covering has not sufficient insulating power to resist it. If the cotton covering were doubled or soaked in shellac varnish, paraffin wax, &c., it would, of course, prevent more resistance; but the processes would thicken the wire and remove the secondary layers too far from primary and core, diminishing induction and lessening spark. Galvanometers, &c., can be wound with varnished, cotton-covered, thin wire, as the tension is comparatively small, and it is, of course, much cheaper than silk-covered. How an ebonite tube is to be made out of sheet-iron is, I confess, beyond me. If sheet-ebonite is meant, the reply is "Yes."—B. HARCOURT.

[61551.]—**Flow of Water through Pipes.**—Size of pipe required would be inversely as the velocity, and the velocity may be found thus:—$V = 97{\cdot}05 \sqrt{R\,S} - 0{\cdot}08$ (Prony) where R = mean hydraulic depth in feet = area ÷ wet perimeter $= \frac{d}{4}$ for circular section of pipe

S = sine of slope $= \frac{H}{L}$
H = head of water in feet
L = length of pipe in feet
d = diameter of pipe in feet
v = velocity in feet per second.

—ELAG.

[61552.]—**Flat Foot.**—I know two young boys with weak insteps, threatening flat foot as they grow. They wear boots which have the space under the instep quite filled up with leather from heel to toe, so that the foot rests all along on a firm bed.—T. F. S. T.

[61552.]—**Flat Foot.**—Impossible for any correspondent to say exactly what is the matter with your foot. Flat foot is generally the half-way stage to a far worse deformity, and may very probably be cured now if you see a medical man at once, instead of tinkering it with the nostrums of well-meaning, but incompetent, correspondents. —REYMOND.

[61554.] — **To Mr. Bottone.**—Your 30c.p. dynamo is doing fairly good work. Still, it will certainly do better in every way if you can get on ½lb. No. 20. The No. 24 opposes useless resistance. Three 10c.p. lamps are easily lit by such a machine. —S. BOTTONE.

[61556.]—**Substitutes in Photography for Glass.**—Stanley, London Bridge, sells paper for use instead of glass for negatives, and frames for using it in ordinary cameras. Yes, you can have carriers to take plates as small as you like, so long as their face is kept in the proper plane for focus. —T. F. S. T.

[61556.]—**Substitutes in Photography for Glass.**—If "Iris" will take the trouble to look through the indices, he will find that so far from there having been little on this subject in your pages, there are many articles descriptive of patented and other substitutes for glass. Let him look in No. 1114, p. 475, for instance.—T. J. M.

[61556.]—**Substitutes in Photography for Glass.**—Get the *British Journal of Photography Almanac*, price 1s., and you will find many experienced opinions on the subject. (2) Yes, certainly; any size smaller can be taken by means of carriers, and you can make them yourself out of an old cigar-box.—B.SC., Plymouth.

[61556.]—**Substitutes in Photography for Glass.**—(1) What is it that you want to know? Eastman's paper and Pumphrey's "flexible glass" are generally considered the best substitutes; the difficulty in the case of the paper is to get rid of the grain. Except for the weight, paper films have no very great advantage which glass does not possess, and they have many disadvantages. You can take any intermediate sized plate by means of carriers—thus with a ½-plate camera you can take full size, 5 by 4, 4¼ by 3¼, and 3¼ by 3¼ negatives.—R. A. R. BENNETT.

[61560.]—**Engineering.** — This is a most important query for parents having sons about to enter practical life in the profession, and I trust friends of "Ours" who are in a position to give particulars as to the mutual obligations of the firm and of the pupil will kindly do so, for the benefit of the interested, but oftentimes uninitiated, of which I am one.—MARIENBERG.

[61561.]—**Gravitation.**—Since the force (if it be a force) called the "force of gravitation" has never been known to suddenly take hold (so to speak) of a body of which it had not hold before (for the simple reason that it has always, as far as is known, had all known bodies in its possession since they were first known), the velocity with which it would do so has not yet been determined accurately, but is estimated roughly at about $\frac{00}{1}$ miles per $\frac{1}{00}$ seconds. I myself have, nevertheless, seen no mention of this in any works with which I am acquainted.—ANOTHER DISGUSTED.

[61563.]—**Torricelli's Theorem.**—Four cubic feet in 30 minutes $= \frac{4}{30 \times 60}$ c.ft. per second, or a stream $= \frac{4 \times 144}{30 \times 60}$ sq.in. of section per second; velocity of efflux from vessel per second $= \sqrt{2gh} = \sqrt{64 \times 4} = 16$ft., ∴ effective area $= \frac{4 \times 144}{30 \times 60 \times 16} = {\cdot}018$sq.in. The actual opening would need to be larger by about 10 per cent.—T. C., Bristol.

[61563.] — **Torricelli's Theorem.** — Where v = theoretical velocity due to head of water in feet per second $= 481{\cdot}5 \sqrt{H}$
Q = quantity of discharge in cub. ft.
E = velocity of efflux
K = coefficient for orifice (for hole in thin plate $= {\cdot}62$)
A = area of hole
$E = VK \qquad Q = EA$

$$A = \frac{Q}{E} = \frac{{\cdot}0022}{963 \times {\cdot}62} = \frac{{\cdot}0022}{597{\cdot}06}$$
$$= {\cdot}0000037 \text{ square feet}$$
$$= {\cdot}0005328 \text{ square inches}$$
$$\therefore \text{diam.} = {\cdot}0005328 \div {\cdot}7854 = {\cdot}00068$$
$$\text{diam.} = {\cdot}00084246 \text{ inch.}$$

—ELAG.

[61563.]—**Torricelli's Theorem.**—A stream of water flowing through a small orifice in a thin plate at the bottom of a wide vessel naturally contracts itself, and it is found by experiment that the smallest section of the stream is below the orifice at a distance of about half its diameter. This point is called the "Vena contracta"; the diameter of its section is about $\frac{4}{5}$ths of that of the orifice, so that about $\frac{5}{8}$ths of the water would flow through the section, as compared with what would otherwise be due to the size of the orifice. Taking then A as the area of the section of the vena contracta, and V as the velocity of the stream at that point, the volume of water that would flow through the section in one second would be—V A and in 30 minutes the volume would be—180 V A,

$$\therefore 180\,V A = 4 \text{ cubic ft.}$$

But V is the velocity due to a fall of 4ft.

$$\therefore V = \sqrt{2g \times 4} = 16 \text{ nearly}$$
$$\therefore A = \frac{4}{16 \times 180} \text{ sq. ft.}$$

$= {\cdot}5$sq.in. And the area of the orifice $= {\cdot}5 \times \frac{8}{5} = {\cdot}8$sq.in. The radius of a circular orifice would, therefore, be slightly over half an inch.—MILVERTON.

[61564.]—**Instantaneous Exposures.**—TO S. BOTTONE and "B.SC., PLYMOUTH."—If the plates are really under-exposed with the exposures given, there must be something wrong with the plates. To certify this, try another brand, say Sykes' "Albert." If the results are the same, the developer then must be at fault, and your only remedy will be to make up a fresh batch, or change developer altogether.—S. BOTTONE.

[61564.] — **Instantaneous Exposures.** — I founded my opinion that you had over-exposed on my own experience. I will now give you the time worked out by "Platt's Systematic Exposure Tables." The circumstances you give are ("Subject and Light") Panoramic View and Sunshine = 1 in Table I. ("Time") 12 o'clock summer = 1 in Table II. ("Lens and Stop") R.R.S. lens, full aperture, F 10 = 1 in Table III. ("Plate") you don't say which; but supposing it is a slow one = 20 in Table IV. The formula now stands thus: $1 \times 1 \times 1 \div 20 = \frac{1}{20}$th of a second; you exposed for 5 seconds, therefore you have over-exposed 100 times. Beach's developer is very good for instantaneous work; make up a new one, and see that your sulphite of soda is pure and fresh, and not sulphate, because that may be the cause of the slow development, notwithstanding the fearful over-exposure. A rapid portrait lens is, as you found it, far quicker than an R.R.S. lens; but then you can't take a landscape with it.—B.SC., Plymouth.

[61565.]—**Daniell's Battery.**—I find by experience that the Leclanché battery is more economical, needs less attention, and is equally if not more permanent than the Daniell's. For electric-bell work I should certainly always use the Leclanché. I think that it will be found that the Post Office more generally adopt the Leclanché by preference.—H. A. B.

[61565.]—**Daniell Battery.**—To prevent the salts creeping up porous-pot, take a new one and heat it before the fire till nearly 100° C., or so that you could just lift it; stand it thus, mouth down, in melted paraffin wax, and let it stand, say, 2in. deep till the wax commences to freeze, then take out and wipe superfluous wax off. If you want the cell for such work as you name, then charge it inside porous-pot with water only, and outside with water and copper sulphate; then connect the two wires together for three hours before you require to use it. Put the cell inside a box to prevent evaporation.—OHM.

[61565.] — **Varnish for Accumulators.** — "Volt" should try Scott's hardened rubber varnish. If two or three coats applied, he will find it very good.—OHM.

[61566.]—**Difference between Shunt and Series.**—TO MR. BOTTONE.—This query recurs about once a month. I send this time a reference to the place where I last figured and described a series and shunt-wound machine—viz., "E.M.," Vol. XLIII. p. 466, No. 1,113. With regard to getting different powers from a dynamo, it can be done, as you suggest, in a series-wound machine, by putting on each layer of the F.M. wires, in separate strands, which can be connected at will by means of a switch. If only one layer is used, the current is of the lowest E.M.F.; but if all the layers are connected in series, it is of the highest. But a machine as small as described by you will not give sufficient E.M.F. for physiological effects, unless, indeed, you employ an interceptor to break the current, or short-circuit it, as described in my last article on "Electrical Instrument-Making for Amateurs."—S. BOTTONE.

[61567.]—**Strength of Materials.**—Was not this answered a week or two back? Taking the tensile strength of iron at 22 tons sq. in. of section, the strength of any piece of iron in tension is directly proportional to its sectional area, whatever its sectional shape may be.—T. C., Bristol.

[61567.]—**Strength of Materials.**—Here is another "Novice," who may be recommended to the textbooks for an answer to his query. If he will give the dimensions of his pieces of iron, he may possibly receive an answer.—VIDEO.

[61567.]—**Strength of Materials.**—This query is indefinite, insufficient particulars being given; but if the iron is to be compared for crushing or tension, the proportional strengths will be as the areas are to one another; if for girders, multiply breadth in inches by the square of the depth in inches of each sample, and compare results. Thus a section 2in. × 6in. deep is four times as strong as 2in. × 3in. deep; thus, $2 \times 6^2 = 72$, and $2 \times 3^2 = 18$. —G. J.

[61568.]—**Gold.**—In colouring gold, the tone of the colour depends upon the alloy, and as the dish that "Dublin" has to repair is probably one of the old-fashioned kind, made from gold alloyed with copper only, he will either have to get a piece of gold as near the same as possible, or melt and roll out a piece to suit, as unless any two bits of gold are very near the same in quality and alloy, they can never be made to have the same tone of colour so as to stand wear or use.—DENS.

[61568.]—**Gold.**—Fine gold can be alloyed to many different colours and qualities. "Dublin" does not say what carat the dish is made of; therefore I cannot tell him the alloy he requires. The dish may be 9, 15, or 18 carat. If he will publish his address and the quality of gold the dish is made of, I will send him the alloy he requires; but if he would take my advice, as I see he is a novice as regards alloying gold to a particular colour, he should cut two or three grains off the dish, and send the cuttings to any refiner, with size of piece he requires, or take the dish to the refiner, and he will match it at far less cost than Dublin can.—DUNCAN.

[61571.]—**Organ Accordion.**—If "Derfla" will advertise his address in Address Column, I will send him a drawing of a good arrangement free by post; or if a drawing would be of sufficient interest to the readers of "Ours," I will send it to the Editor for insertion in the "E.M."—G. FRYER.

[61572.]—**Wimshurst Machine.**—TO MR. BOTTONE.—Yes, the mode suggested by you will be efficient. It is well that the two outer coatings should be metallically connected by means of a strip of stout tinfoil.—S. BOTTONE.

[61573.] — **Microscope Lamp.** — If "Neo-Microscopicus" will remove the metal chimney from the lamp directly after use, and only replace it at the time he wishes to light the lamp, the evil will be cured. The cause of the unpleasant smell is the heating of the chimney, on which some of

the volatile paraffin oil has been condensed.—EDWARD M. NELSON.

[61574.] — **The Calculus.** — "Tyro" should imagine a square magic-lantern sheet before him, which in a very magical way is growing bigger and bigger—as in a nightmare—and yet preserving its square form. By some magic law each edge of the sheet grows longer, so as to gain a yard in length in each second, at a steady pace. It is then obvious that the lapse of each second adds also to the area of the sheet. But the area does not, like the edge, increase at a steady pace, such as, say, 30 square feet gained every second: the area grows at a rate which depends on the size of the sheet at the time. The bigger the magic sheet gets the more rapidly it gains in area. "Tyro's" problem is: At what speed is the magic sheet growing in area just at that critical moment when its edge is 10ft. long? and the calculus answers, 60 square feet per second. This result will appear reasonable on inquiring (1) how many square feet will be added in the second then commencing? and (2) how many have been added in the second then elapsing? 1. Edge 10ft. becomes edge 13ft.; area from 100 square feet to 169 square feet; gain = 69 square feet during the second. Average rate during the second naturally greater than rate at commencement of the second, seeing that the rate is continually getting faster. 2. Edge 7ft. becomes edge 10ft.; area from 49 square feet to 100 square feet; gain = 51 square feet during the second ending at the critical moment in question.—WEALD.

[61574.]—**The Calculus.**—This is a question in "fluxions," a branch of mathematics which gave rise to the differential calculus. The lengths and areas we are dealing with are supposed to vary continuously or to "flow" at a steady rate instead of by fits and starts as supposed by "Tyro." In this case the side of a square increases uniformly at the rate of 3ft. in a second, and we require to find at what rate the square itself is varying when the side of the square has arrived at any given length. Suppose the side to have arrived at a length of 10ft., then suppose it to go on increasing for a very small distance, say $\frac{1}{10}$th of a foot or ·1ft. Now, as the side is increasing at the rate of 3ft. in a second, or 1ft. in $\frac{1}{3}$ of a second, it will increase ·1ft. in $\frac{1}{30}$th of a second, and the increase of the square itself in that time will be $(10\cdot1)^2 - 10^2 = 2\cdot01$ square feet in $\frac{1}{30}$th of a second, or $30 \times 2\cdot01$ square feet in one second, or 60·3 square feet in a second. Now, if we had taken our small distance at less than ·1ft., say, ·01ft., our result would approach still nearer to 60 square feet per second, and if our small distance became infinitesimal, the result would tend to 60 square feet exactly as the limit. Put in the language of the differential calculus, the above would be stated as follows:—Suppose x to be the side of a square and y the area of the square, then we have the equation $y = x^2$, and suppose x to be increasing at the rate of 3ft. per second, and consequently y to be also increasing at another rate, and suppose x to have arrived at a certain known length x_1, then to be allowed to go on for a very small distance $\triangle x_1$, and then stop; then the time it would take to do this short distance would be $\frac{\triangle x_1}{3}$ seconds. Now, in this short time y has also been expanding, and we may call the small quantity that it has expanded $\triangle y$; the square has, therefore, expanded $\triangle y$ square feet in $\frac{\triangle x}{3}$ seconds, or $3\,\frac{\triangle y}{\triangle x}$ in one second. Now, suppose $\triangle y$ and $\triangle x$ to become infinitesimal, then the square expands at the rate of $3\,\frac{dy}{dx}$ in one second, or three times the differential coefficient. The differential coefficient of x^2 is $2x$, so the rate of expansion is $6x$.—M.I.C.E., Bath.

[61574.]—**The Calculus.**—"What has time to do with the increase?" It is not asked, What is the increase, but what is the rate of increase? Time is concerned in the answer, inasmuch as it is part of the question: "the side increases at the rate of 3ft. per second; at what rate is the area increasing, &c.?" Answer = at so many ft.^{2} per second. That's where the calculus comes in. The side increases uniformly, the area does not. Suppose the side started from 0: at the end of 2nd second, side = 6ft., area = 36sq.ft. During the 3rd second, side increases 3ft., area increases 45 sq.ft. During the 4th second, side increases 3ft., area increases 63sq.ft.—that is, the area increases 45ft. during one second, 63 during the next, &c., &c. For each fraction of a second the side increases exactly the same as it did for the previous fraction, while the area increases more than it did during the previous fraction. The side has a uniform increase, the area has an increasing increase; therefore, it has a different increase for every point in the side. It is very easy to say how much the area increases from the end of the 3rd second to the end of $3\frac{1}{3}$ seconds (or from 9ft. side to 10ft. side), as "Tyro" has done—that is, during the $\frac{1}{3}$rd of any second (as "Tyro" says, during that $\frac{1}{3}$rd of a second it increases 19sq.ft.); but at the end of the $\frac{1}{3}$rd second it is increasing faster than at the beginning—i.e., more per fraction of time. And it is this which is wanted, the time being given in seconds. It is more than I can do, too; but, short of the calculus itself, I will give "Tyro" any further assistance I can.—M., York.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

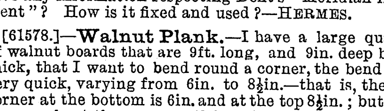
QUERIES.

[61575.] — **Indicator Diagram Puzzle.** — Will some kind correspondent give me information and explanation of these circumstances? I took three pairs of cards from engine with steam jackets on (these jackets drain or return to boiler). Boiler pressure, 16lb.; vac. by gauge, 25·1in.; bar., 28·8in.; revolutions, $20\frac{1}{4}$ per minute. Av. press. of cards (three) gave 10·725H.P. = 63·75. I close jacket cocks on boiler and drain jackets, leaving drain cock open, and after two hours I took three other pairs of cards. Let me here remark this is from a pumping engine, and the load certain. The cards in their figure to the eye had not altered a single phase; but here comes the point or puzzle: The boiler press., 16lb., same as before; vac. gauge, 24·9in., slight fall; bar., 28·8in., same; injection water in both cases the same, 50°; but jacket on, hotwell temperature, 98°; jacket off, 102°. Speed had fallen to 18·75 revs. per min., and av. press. in cylinder 10·74lb., H.P. 58·43. Now, with an increased average pressure in cylinder and load the same, cut-off same, boiler press. same, initial press. and release the same, we have a decrease in speed and an increase in the hot-well temperature, the injection flow remaining the same, being from main through meter.—WATER THUMPER.

[61576.]—**Chimes for Grandfather's Clock.**—I am fitting chimes into a grandfather's clock. I wish it to sound the same notes and in the same time as the clock in the tower of the Houses of Parliament at Westminster. Will someone kindly tell me the notes—their time and order? Also what size and length of steel wire I must have for each particular note.—EIGHT-DAY CLOCK.

[61577.]—**Meridian Instrument.**—Can any reader give any information respecting Dent's "Meridian instrument"? How is it fixed and used?—HERMES.

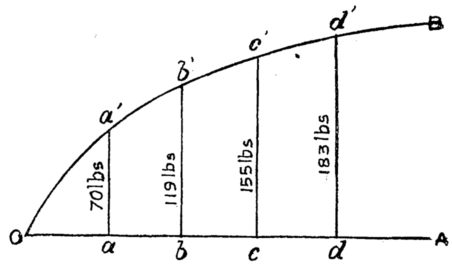
[61578.]—**Walnut Plank.**—I have a large quantity of walnut boards that are 9ft. long, and 9in. deep by $\frac{3}{8}$in. thick, that I want to bend round a corner, the bend being very quick, varying from 6in. to $8\frac{1}{2}$in.—that is, the bend corner at the bottom is 6in. and at the top $8\frac{1}{2}$in.; but when they are bent they are parallel at the top and bottom, and have to be cut out on a sort of sweep before they are bent, something like rough sketch, and at the points A and B



they are a bit on the cross grain of the wood, and at these points, many of them, say about 75 per cent., crack, or break right off, or splinter. The mode I have of doing them is this: I put them into an iron cylinder and close up the ends, and let steam into the cylinder from a boiler at 60lb. pressure, having first filled the cylinder with water, and let them remain there for from three to six hours, and then I take them out and put them into a vice made the shape I want them bent, and by pulling up the jaws against the wood I am able to squeeze them to the required shape; but the trouble is the splintering and breaking of sometimes one end and sometimes the other. Will any of our kind readers help me? Are there any chemicals that I could put into the cylinder that would make the walnut slabs more pliable, to prevent the cracking and splintering, or can any other way be pointed out, as this walnut wood is very expensive, and the failure in each case costs about 15s.? I will be glad if any friend of "Ours" can help me out of the difficulty. I have back numbers from 1881.—JOE BLAIN.

[61579.] — **Storage Cells.** —I have made a trough case of five storage cells. Divisions are glass, and painted inside with marine glue. Each cell contains five lead plates, 4in. by $3\frac{1}{2}$in., alternate plates connected so as to form four faces to each "pole." Please say how I should set about forming. I did as Mr. Conry advised, *re* nitric acid, and have spent some time with a good current, but cannot get signs of formation. Is it of any service continuing charging after the gases have commenced to be evolved? In my cells, gas comes off almost immediately on commencing to charge. Should they be connected in parallel to charge, or is that only to be done when charging current is too low E.M.F.? How many ampère hours?—ANOTHER READER.

[61580.]—**Helical Spring.**—Would a reduction of section of the metal of which a helical spring is composed, from the outer end towards the centre, cause a diminution of increments of tension as the spring is wound up? I wish to obtain a spring, in a drum about 2ft. diameter, which will give approximately the subjoined diagram of



tension. *Oa*, *ab*, *bc*, *cd*, show the amount of circumferential movement of the drum for each revolution, and *aa'*, *bb'*, *cc'*, *dd'* the amounts of force to be exerted by the spring at the circumference. Is there any book on the subject?—HELIX.

[61581.]—**Telephone Switch.** — Can any reader inform me how to make a switch for a central of A, B, and C stations, so that central station B can communicate with A or C separate, and for B to be able to couple up A and C? The greatest difficulty to me is how can A or C tell central B they have finished communication, unless B's bell is always in the circuit? — EN-SWITCHED.

[61582.]—**Chloride of Mercury for Battery.**—To "SIGMA."—Is there any reason, apart from the expense, why chloride of mercury (corrosive sublimate) should not be used instead of the sulphate for a single-fluid battery?—F. R. R.

[61583.]—**Castings.**—Can any reader inform me the class of metal that is used in making children's toy metal tea sets? Also, what metal is the mould for casting usually made of?—CATHODE.

[61584.]—**Stamping.**—I am about making a quantity of medals about the size of a penny piece out of soft metal. Could any reader give an idea of the size press I should require to stamp these up? I have one, but it is too small; but it will do for cutting the blank pieces out before striking up the design on the sides. Not knowing anything regarding power of presses or amount of power required for stamping medals, I should be thankful to receive whatever help you may be pleased to give.—G. H.

[61585.]—**Polishing Fretwork.**—I have some fretwork in walnut to polish. I have treated the wood in the usual way: first with linseed oil, then with wax and turpentine, then with Harris's French polish; but there is no gloss. Will one of our experienced readers help me, and also tell me how to treat the edges?—ONE IN A FIX.

[61586.]—**Waterwheel.** — Will some fellow-reader kindly tell me whether 14gal. of water per min. coming through a 3in. pipe with a 10ft. fall upon an "overshot" waterwheel, 3ft. diam., 18in. wide, is sufficient to pump 1,000gal. of water in 24 hours with a $1\frac{1}{4}$in. force pump through 1,000ft. of 1in. piping and to a height of 100ft.? If it will do it, kindly give formula.—ZULU.

[61587.] — **Street Medical Coil and Phonograph.**—I have no doubt there are others besides myself who would be glad of instructions to make, and a sketch (to scale) of a good street medical coil, and also the phonograph. I am anxious to make both, but uncertain how to start. Some of the coils have a wheel revolving or bell ringing. I want to make for a bazaar. Will someone kindly assist?—COUNTRY.

[61588.]—**Brass-Cleaning Composition.**—I have noticed the G.N. carriage cleaners at Peterborough rub the carriage door brasses with some composition which gives a good polish to the most tarnished metal. Can any of "ours" state what it consists of? Having a deal of brass-work to clean, should find it useful, as might also other readers.—COUNTRY.

[61589.]—**Coal Economy.**—In your issue of the 14th ult., under the above heading, "Nun. Dor." empties the vials of his contempt on the sugar refiner who used 900 tons coal to refine 1,800 tons of sugar weekly. Now if "Nun. Dor." can show in what manner this quantity can be lessened, I feel sure that every refiner in the world would gladly adopt his suggestions. I do not know what power said refiner used; but I do know that in a refinery working about 400 tons weekly it is nearly 130 horse.—CANE SUGAR.

[61590.]—**Electrical Footwarmers.** — Can any correspondent give me any information concerning the above, as to working, and construction, current, and E.M.F. required, &c., particularly that of Mr. Rabache, about which a reply appeared in "Ours" lately?—EDWARD CONRY.

[61591.]—**Lifeboats.**—What is the maximum number of lifeboats carried by any man-of-war, taking the definition of a lifeboat to be a boat fitted with special apparatus to enable her to ride out a heavy sea and venture out in such for the saving of life, and regarding such boats as distinct from the ordinary boats of the ship intended for the usual purposes of marine conveyance?—EDWARD CONRY.

[61592.]—**Tinned Steel Spiral Springs.**—Would any of "ours" be kind enough to say if tinned steel (1-16 wire) spiral springs keep their spring pretty well?—LIGHT WEIGHT.

[61593.]—**Electro Deposition.**—In an article in "Ours" on "Electro Deposition," by Watts, I see you speak of lead being deposited under a process known as Nobili's rings. Could you give me full details how I could do this, and if it would be possible to procure this on tin? I find that when Banka tin is recast and rolled out as fine, some of it is smooth and other parts granular, and as this prevents it being rolled out very thin, I desire to find some means of checking. The smelters say that it is caused by the metal being cast at different temperature. Could this be the reason, and, if so, say at what temperature it should be cast for granular? I must also add that pure Banka tin is used without any alloy. I also desire to know if I could deposit tin, lead, or antimony in a crystaline form on tin foil? I have tried the two back numbers mentioned, but have not succeeded (that is, dilute nitric acid and hydrochloric acid, also tartaric acid with hydrochloric acid). Do you think that acid and tartarate of tin and caustic potash would do for it? I think I saw this in a book. Where I work, we use a large reverberatory furnace for converting lead and tin dross into lead and tin; but we find, with all the precaution of dovetailing the firebricks and using good fireclay, that the metal runs out in large quantities. Could anyone help me?—CAMMIADE.

[61594.]—**Walcot Battery.**—TO "SIGMA," OR OTHERS.—Can I get the constant of tangent galvanometer by a voltameter or closed Smee cell (as described by you in your "Electricity") in chemics and ampères, single ring 18⅝in., needle 1⅛in.?—STUDENT.

[61595.]—**Lead Burning.**—Will some brother reader kindly tell me how to join the corners of a small lead box without soldering? Can it be done without the aid of a blowpipe, as I do not possess one? The lead is 4lb. to the foot, and the joints must be perfectly liquid tight.—ARCADIAN.

[61596.]—**Goniostat.**—TO MR. EVANS.—I am thinking to try to make a goniostat after Mr. Evans's instructions, Vol. XXXV. No. 888; but there are two or three little matters which do not appear quite clear. It is not stated of what material the plates and some other parts are constructed. He says: "Before proceding with the steel parts." It may therefore be assumed that some of the parts are not steel, but it is not stated which. He also says in one part that 3-16th Whitworth threads, as a rule, will do for the screws; but almost immediately afterwards says: "I will take it that these—viz., ¼ Whitworth, shall be considered the threads throughout." But the most important omission appears the omission of any directions for cutting the graduated degrees on the arcs, and without which the instrument is, of course, quite incomplete. Perhaps Mr. Evans will kindly add to our obligations to him by supplying this information.—B.

[61597.]—**Organ Pipe Scales.**—Is there any rule for making pipe scales? For instance, I have a length rod; but if I make a larger scale, my pipes are too long, and if I make a smaller one they are too short. Cannot I know at once what the lengths ought to be if I decide upon certain depths and widths?—B. BOLT.

[61598.]—**Hall Mark.**—Will someone of your numerous readers kindly give the date and country of the following Hall mark, which occurs on a standing cup, in the Renaissance style? Beginning at the left, the first mark is the numeral 13 in Court hand, then follows an anchor with a rope attached, then what appears to be a human head, then a lion rampant, then the maker's initials, two capital L.'s back to back, which I take to read J. L. The latter is in a sexagonal shield; all the rest in circular or oblong.—ARGENT.

[61599.]—**Gunmetal.**—Would someone kindly say how to mix gunmetal, as I wish to try some castings, such as bicycle hubs?—BLACKSMITH.

[61600.]—**Cone for Lathe.**—I have a 3in. backgeared lathe, with three speeds—viz., 2⅞in., 2 5-16in., 1⅝in. Would someone kindly say what size of a cone I would require to work on crank-shaft not to have the belt to shift? I wish to make the smallest size 6in.—BLACKSMITH.

[61601.]—**Decomposition of Carbonates.**—Can carbon or acetylene be obtained from carbonates by heating them to a sufficiently high temperature in an atmosphere of hydrogen, and what degree of heat is required?—ALPHA.

[61602.]—**Pile Driving.**—Will one of "ours" kindly give a description and good sketch of Doherty's patent ram for pile-driving, or any other kind of approaching automatic "monkey," not forgetting to find fault, if needed?—GUILLAUME BOIS.

[61603.]—**Reduction of Numbers.**—Can any reader tell me whether any number containing, say, from 10 to 60 figures can, by some method, be reduced step by step to one of two figures in such a manner that, by reversing the method, the original number can step by step be worked up again from the two figures found? I have to work with numbers of great compass (I mean by this, containing a great many figures), to which logarithms are wholly inapplicable.—REDUCTION.

[61604.]—**Chemical Equivalents.**—Is there any chemical book or tables of these published giving the complete symbols and combining proportion of all the usual metallic salts and their water of combination and crystallisation, as, doubtless, many besides myself would be glad of being relieved from unnecessary calculation?—VULCANITE.

[61605.]—**Jerusalem.**—Will any subscriber kindly inform me if he has visited Palestine, and date when, or has executed work in that country? The cost of lodgings and living there, and if the climate is healthy? Also, what quality or kinds are the stone? Also the various woods?—JAFFA.

[61606.]—**Railway Fish-plates.**—Is there any advantage in having fish-plates clip under the rail, and, if so, what? When were fish-plates invented, and how did they join the rails before the introduction of the fish joint?—STUDENT C.E.

[61607.]—**Proportions of Locomotives.**—What proportion should the cylinder of an engine bear to the boiler or heating surface?—INQUIRER.

[61608.]—**Compound Engines.**—It is often said that the compound principle is best for goods engines because they run at a slower speed. Now we know a goods engine runs at a less speed per hour by reason of its small wheels; but does not a goods engine make as many revolutions per minute as the express engine?—LOCO.

[61609.]—**Warming Railway Trains.**—I think every one who has had the bad luck to ride in trains this winter will say our railway carriages are fearfully cold. What plans are there to warm them, either by exhaust steam from engine, or by gas or hot water?—HALF FROZEN PASSENGER.

[61610.]—**Circular Saw.**—I have two Howe sewing machines, toothed wheels—two 8in. diam., four 2in. diam., with spindles. What thickness of wood will those wheels cut with an 8in. circular saw? Also, how are the wheels to be placed to run?—J. T.

[61611.]—**Improving Clay for Pottery.**—Can ordinary white bricks and white chimney-pots be made of clay such as would make common stock bricks? White brick is made by Cubitt's at the Isle of Dogs. The clay there must be very poor; and I am told they grind up broken crockery from dust-hole refuse for the purpose. If so, what sort of mill would be used? Doulton's and Stiff's both make chimney-pots of a light-coloured clay at Lambeth. Can anyone say where it is obtained?—MURANO.

[61612.]—**Food for Animals.**—Will someone please tell me which of the following (or any others) is the best to feed calves or pigs on, not to fatten, but to make them as large-framed as possible: Beans, peas, barley, oats, pollard, bran, or will any of the patent foods give the desired effect better? Does skimmed milk added improve matters in case of growing pigs?—THOMAS.

[61613.]—**Dynamo and Continuous Current Battery.**—Will a dynamo giving, say, 40 volts and one or two ampères answer the same purpose for medical uses as a battery coupled up in series to give the same amount of current and E.M.F.?—F. G.

[61614.]—**Clutch.**—Would any reader give me illustrations of the clutch—how it is thrown in and out of gear, and how it is fitted together for screw-cutting lathe?—A. SEDGLEY.

[61615.]—**Porcelain Clay.**—Can any correspondent inform me where this can be obtained, and if any special knowledge is required in treating same for moulding and baking, or if special furnace is needful? I am desirous of making some insulators of a particular form, and should like them to be of this material, or of vitrite or glass.—H. T. C.

[61616.]—**Gramme Dynamo.**—I have a Gramme dynamo, fields wound with 40lb. 20d.c. The pole-pieces will take in an armature 6in. dia. What ought this to be wound with to give 20 by 20c.p. lamps easily? The armature preferred would be a Gramme ring made from iron wire. The total resistance of wire on fields is about 70 ohms.—A. B.

[61617.]—**Removing Ink Blots.**—A so-called "fluid ink eraser," which causes ink blots and marks to disappear, is being sold in shops. Of what is the solution composed?—X.

[61618.]—**Variable Pitch Propeller.**—How is this propeller shown on a working drawing? I understand and can depict a true screw.—GIL BLAS.

[61619.]—**Varnish.**—I want to find out which varnish will stand the greatest amount of heat. It is to be used in combination with asbestos. Will any of our experienced readers give me results from practical experience?—OILMAN.

[61620.]—**To Mr. Bottone.**—I am making small dynamo with laminated H armature, but do not know how to fix sections of armature on rod. Will you kindly advise me?—FIXED.

[61621.]—**Dividing a Circle.**—Will any reader tell me how to divide a circle geometrically into any number of equal parts, say three, (1) by lines drawn parallel to any given diameter, (2) by lines drawn from any given point (other than the centre) to the circumference?—A SUBSCRIBER.

[61622.]—**Planetary Drawings.**—Would any of your readers kindly inform me how the dead black representing sky is obtained in planetary drawings? I have been trying Indian ink, but not very successfully. What paper is generally used, and where obtained, and what colours employed? I allude especially to the fine sketch of Saturn presented by Mr. Green to the Royal Astronomical Society; also the beautiful sketches of Venus, showing phosphorescence of the dark side. How is the transparency of Saturn's crape ring best rendered? The Merope nebula, which many observers affirm they have seen with small apertures, is not nearly so large or conspicuous in Mr. Roberts' photograph as that surrounding Maia, Alcyone, and Electra; that round Maia seems by far the largest, judging from the photograph.—CONSTANT READER.

[61623.]—**Legal and Revenue.**—Receipt for succession duties paid seven years ago has been lost. Is it necessary to show a receipt for these duties on selling any portion of the property? If so, how can one be reobtained?—SUCCESSOR.

[61624.]—**Speculum.**—I have been grinding and figuring a speculum, but am rather disappointed with the result. It gives a perfectly defined image of the moon, and the sun also; but when it is placed on Saturn, or any star, the image is ill-defined and woolly. Under the shadow test, the curve is certainly parabolic; but is the correction carried too far, or the reverse? The shadows are not very dark when the speculum is under test.—ETANIN.

[61625.]—**Chemical.**—Will some chemical friend kindly inform me how to make ozonic ether? I can procure hydrogen peroxide of 20 vols. strength.—OZONIC ETHER.

[61626.]—**Assaying of Ores.**—Will some of your numerous readers give me advice as to becoming capable of assaying gold, silver, lead, copper, and blende ores—that is, to make the shortest way without going to the Royal School of Mines to have a thorough course, but the quickest way? I have a knowledge of the different ores. What time would it take me? What books and instruments would it require?—CYMRO.

[61627.]—**Boring Hard Wood.**—Will one of your numerous mechanical subscribers kindly describe the best bit or tool for boring hard wood? The hole I want is 1⅝ dia., and wood 1⅛ thick. I have been using a centre bit, speed about 2,000 revs. per min.; but it spalters off about 1-16 of wood on the under side, which I want to avoid.—H. F.

[61628.]—**Lard Oil.**—I use a good quantity of English lard oil in my work, which at present time is an item considering the competition in the manufacturing line. I therefore bought, through the "E.M," Sixpenny Advertising Column, several recipes how to make substitute for lard oil, but none of these turned out of any value. I should like to learn the experience of others in this matter. Can any of your numerous readers direct me how to make, say, from American lard, which I can get at a very low figure, a good substitute for English lard oil? I shall be very much obliged, and would publish the result.—MACHINE TOOLMAKER.

[We have ourselves found Bell's asbestos lubricant the best substitute for lard oil in connection with our printing machinery, after trying a good many things.—ED.]

[61629.]—**To Analysts.**—A sample of flour is supposed to contain a mineral poison—viz., As, Sb, Cu, &c. How can it be got into solution so as to estimate it? Could the sample be treated with dilute HCl, filtered, and the filtrate treated with the group reagents? I know the method of treating the ash with HCl, &c.; but find it very tedious, as such a large portion of the flour has to be taken to obtain sufficient ash. How can strychnine be detected and estimated in flour, &c.? Will the method of detecting and getting into solution prussic and oxalic acids in viscera hold good for flour, oatmeal, &c.?—X. Y. Z.

[61630.]—**Loss of Power in Model Lifting Crab.**—In a model of a lifting crab, the circumference of the circle described by the end of the winch handle is 43in., and the circumference of the drum which raises the weight is 14·9in. The wheel work gives an advantage of 8 to 1, and it is found by trial that a power of 3·1lb. on the winch handle just suffices to raise a weight of 56lb. hanging on a cord wound round the drum. What proportion of the power exerted is lost in this model?—S. B.

[61631.]—**Whiskey Distilling.**—What is the greatest strength whiskey is ever made for sale? How strong could it be made for sale if required? What is the greatest strength of the spirit as it comes from the still—e.g., soon after the spirit begins to distil and before much water comes with it?—KANET.

[61632.]—**Specific Gravity of Spirits.**—What proportion of spirit to water is "proof" spirit? What are "degrees" over and under proof, and how is "proof," "over-proof," and "under-proof" to be calculated from the specific gravity? What is the difference between 30° over proof and 3 per cent. over?—KANET.

[61633.]—**Dynamo.**—TO MR. BOTTONE OR MR. CONRY.—I have a series-wound dynamo, which I should like to make into a shunt-wound. The size is F.M. 7in. high 2in. thick, pole pieces 8in. by 3in. wide, with the opening 7¼in., and wound with 10lb. of No. 16 c.c. wire, armature 7¼in. by 3in. wide, Pacinotti type, cast iron, wound in 12 sectors, with 2¼lb. of No. 18 c.c. wire. Will you tell me what quantity of No. 16 to add to it, or would you think it will be best to wind it with No. 18 c.c. wire, and what quantity, and at what speed to drive it at, and what volt lamps to use? I want to run eight 16c.p. lamps.—DIAMINE.

[61634.]—**Will o' th' Wisp.**—Has any living reader heard of anyone who has seen this phenomenon? I had a nursemaid from near Hindon, Wilts, who used to describe it; but, without knowing this literary name, nor "corpse-candles," or any other that we see in books, she called it "Kit candlestick," which was the trade name, early in this century, of a candlestick with a slide; the flames over marshy ground always, according to her, dancing up and down, as if raised and lowered in such a candlestick. Has drainage entirely extinguished Will o' th' Wisp in Britain or everywhere?—E. L. G.

[61635.]—**To "T. C., Bristol."**—I have a 12-horse horizontal engine doing about 4-horse work. Her speed is 90 revs. per min., driving a shaft at 30 revs. per min. Would it be a saving of much steam for the engine to travel same as the shaft? The cylinder is 14in. bore by 20in. stroke. The back-pressure is but little more than the pressure of the atmosphere.—ANXIOUS TO KNOW.

[61636.]—**"Feed" Wick for Paraffin Lamp.**—I have a duplex lamp, with very deep reservoir. The lamp will hardly burn at all except when filled to the brim, and I am told the wick should have an extra wick to act as a feed, and that lamps with very deep reservoirs are so fitted. I sewed two pieces of wick (trebling it), and it burnt very well, but this is manifestly an inconvenient plan. How could I add a feed wick? A sketch would be useful.—MURANO.

[61637.]—**Romsey Observatory—Dewing of Object-Glass.**—Will any practised observer give me his experience of the above kind of observatory? Mine is built according to Mr. Berthon's instructions. It has a space of about 1½in. between top of wall-plate and bottom of dome-ring. A zinc-hood 4in. deep is nailed all round this opening on outside to keep out snow and wind-driven rain. In warm, damp weather the iron pillar and circles, &c., are always covered with moisture, in spite of ventilating space between dome-ring and wall. My dew-cap is of metal, having a cover like a camera-cap, lined with velvet. Should this leather cap always be put on the end of dew-cap when shutting up for night? as I often find the o.g. anything but "bright" next morning. I have been in several well-appointed observatories, and find the owners never cover the open end of dew-cap, and do not complain of dewing. My observatory is all wood, canvas-covered dome. Any hints by owners of Romsey observatories would be gladly received.—H. A.

[61638.]—**Vertical Boiler.**—TO "T. C., BRISTOL."—I have a vertical boiler which is 2ft. 9in. high, 14in. dia., with firebox 18in. by 10in. at top. Is it large enough to work an engine 2in. bore by 3½ stroke, boiler made of ¼ plate? And will you kindly tell me what size hole it will take for the safety-valve, which is a lever valve, and what weight to put on it; and what pressure it will stand; and at what pressure to keep it working to keep it at half-horse? It is to work a dynamo of eight 16c.p lamps.—DIAMINE.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

BACK NUMBERS.

WE receive so many queries asking for directions how to make many instruments and appliances which have been fully described in back volumes, that we have compiled a list, which we shall insert in this column at intervals, of those most frequently sent, and as the numbers are still in stock, new subscribers should consult the list before sending their questions.

Bookbinding : No. 613.
Electric machines : Nos. 1,009, 1,025.
Electro-magnets : Nos. 772.
Lacquers : No. 866.
Pattern Making : Nos. 938, 941, 943, 945, 948, 950, 952, 954, 955, 956, 958, 959, 962, 963, 969, 974, 978, 986, 989, 993, 995, 998, 1,000, 1,001, 1,003, 1,004, 1,008, 1,009, 1,010.
Silver-plating : Nos. 1,009, 1,010.
Varnishes : Nos. 478, 619, 675, 723, 775.

The following are the initials, &c., of letters to hand up to Wednesday evening, Feb. 2, and unacknowledged elsewhere :—

CROSSLEY BROS.—U. Dini.—D. H. Sinton.—W. Yonge.—J. E. H. Andrews and Co.—P. H. Anderson.—S. and Co.—W. H. Smith and Son.—King, Mendham and Co.—W. Stanley.—F. A. Smith.—E. S. Hindley.—Vulcan.—Herbert Ingall.—R. T. Lewis.—A Fellow of the Royal Astronomical Society.—J. H.—Jas. G. Shepherd.—W.—J. S.—Sanderson.—J. R. Campbell.—Garrison Gunner.—R. P.—W. A. T.—Foreman.—Wm. White.—Q. E. D.—J. P., Aigburth.—Electrical Student No. 2.—Iota.

TOR. (A couple of small chloride of silver cells would do; or you could make Leclanché cells up to that size, by special arrangements. Look through the indices of back volumes for directions for making.)—G. M. (You must wait patiently. Inventors, if they are wise, do not describe their devices before the patent has been obtained; for "provisional protection," as it is called, is now only the acceptance of an application.)—H. F. G. (It does not say a "third part," but "three parts," and "parts" means ounces, pounds, or anything else, according to the quantity of the mixture required. 2. About three or four ounces. No coils. See back numbers—p. 561, last volume, for instance.)—T. D. (Culley's "Handbook of Practical Telegraphy," Longmans, price 16s.)—C. (Directions frequently given; but the construction of the coil must be known. See p. 53, this volume.)—SPARKS. (Electric gas-lighting arrangements have been frequently described and often illustrated. For a portable appliance, see p. 403, No. 1033, or p. 391, No. 927. For the stationary arrangement, all that is needed is a little coil of platinum wire over the burners, which is made nearly white hot by the passage of a current from a battery; or, instead of that, two platinum-tipped wires are adjusted close over the burner, and a spark is passed when it is required to light the gas. See indices.)—P. E. A. (Apparently made for some special purpose. No one can do more than guess.)—T. EASEL. (Perhaps you do not rub the work down between the successive coats. The finishing coat must be either a varnish paint, or the work must be varnished as a finish.)—F. W. (See pp. 352, 378, this volume; pp. 348, 390, Vol. XLII.; p. 226, Vol. XXXVII., and the indices generally. 2. You want a "changing bag," for which see pp. 487, 512, last volume, and the indices.)—T. W. WOODHEAD (You might obtain a second-hand copy by advertising in the Wanted Column. Thomé's "Structural and Physiological Botany," published in Longmans' series of Textbooks of Science, 6s., might suit. 2. Would "Coal: its History and its Uses," by Profs. Green, Miall, Thorpe, Rücker, and Marshall, be likely to suit? If so, it is published by Macmillans, 12s. 6d. See Hints No. 5.)—VIR. (A special preparation is necessary, we believe. See p. 392, No. 1032, and p. 226, last volume.)—H. MCC. (Papier-mâché is what its name implies, but it can be moulded up from any pulp that would make paper. You would require powerful machinery to exert the requisite pressure.)—WALTER WHITE. (The only way we know of is to examine the local papers for announcements and advertisements.)—E. CHAPMAN. (You can obtain sketches in some of the trade catalogues. They are made just the same as other rising bellows, except that they are round.)—GREASEY. (No, it is the heavy oils, after the burning oil and paraffin have been extracted. Quantities of it are no doubt brought into your port; but try some of the large dealers in oil, or insert an advertisement in the Wanted Column. 2. Tallow is made from the fat of animals, mainly the ox and the sheep.)—G. WILCOX. (To answer such a question it would be necessary to search the records at the Patent Office. A patent agent would be able to tell you.)—PNEUMATIC SHUTTER. (Many of those illustrated can be made to work inside camera; but to what good purpose?)—C. LESTER. (We might be able to answer your question if you could determine the age of the Runic characters. They were most probably introduced by Phœnicians. See the article "Alphabet," in the "Penny Cyclopædia.")—E. R. DALE. (The calculating machine at the Railway Clearing House is, or was, De Colmar's, illustrated in No. 571. 2. Where is the reference to the gas floating lamp? At present it seems to be unknown.)—A CONSTANT READER. (Silvering on lead is not easy; but it may be accomplished by scraping the lead surfaces clean and immersing in a bath of cyanide of silver solution containing a large proportion of free cyanide. A current of considerable E.M.F. is used, and as soon as a thin deposit of silver has been obtained the articles are removed to the ordinary plating bath.)—E. A. HANCOCK. (If you mean Wheatstone's bridge, in No. 1105, p. 286. See also p. 328, No. 1107.)—MANCHESTER. (Query too indefinite. If you mean that the core is No. 9 thick, use No. 26 or 28 wire.)—TELEGRAPHIST. (See indices. You do not say what is the resistance of the lamps or the voltage they are adapted to. If of low resistance, two or three cells would answer.) — INFORMATION. (Sprague's "Electricity," published by Spons; but see indices.)—NIL DESPERANDUM. (If opening the door is a remedy, it is clear that sufficient air does not otherwise get into the room. You can take a pipe from the outer air to the hearth under the grate, or put in a stove with a chamber at the back, which will draw air from the outside and deliver it warmed into the room. A Boyle's cowl will create a draught if there is sufficient inlet for the air. You will find many suggestions in back volumes.) — ONE WILLING TO LEARN. (Reynolds's "Stationary Engine Driving," Crosby Lockwood and Co., Stationers' Hall-court, E.C., price 4s. 6d.)—DIDDEMEWASS. (One hundred cubic inches of hydrogen at 60° Fahr., and 30in. bar., weigh 2·143 grains; roughly, 13½ cubic feet will lift a pound. 2. The "capacity" of a circle is a misnomer. You mean its area or superficial contents. To find that, multiply the diameter by itself (square the diameter) and multiply again by ·7854.)—A CONSTANT READER, E. T. (An illustrated description of the xylophone in No. 1063, p. 494. Lengths of wood can be found by trial.)—STEREO. (They are supposed to be identical, but in practice the composition varies. Lead 4 parts, antimony 1 part, is the standard; but founders never care to take tin out of any old metal they may buy, but they most religiously exclude zinc. The working temperature is a straw colour on a bit of paper, momentarily dipped into the pot; but if the moulds are of plaster, the metal may be a little hotter. You should have stated the process you are working, and with what plant. Put a small piece of tallow in and stir briskly, when the dross will rise, and can be removed.)—WILLIAM PETERS. (Cannot you put some ventilating gratings in by removing a few bricks from the course just below the ceiling? 2. Do you mean real soap powder? That should be made by shredding Castile soap very fine and allowing it to dry. It is then rubbed through fine muslin. If you mean the so-called soap powders, take yellow soap, 6 parts; soda crystals, 3 parts; pearl-ash, 1½ part; sulphate of soda, 1½ part; palm oil, 1 part. Mix, spread to dry, and grind.)—A SUBSCRIBER, East Molesey. (Your opinion is quite correct. Ice often forms at the bottom of rivers, and is well known as "ground ice." The phenomenon is, perhaps, best known to those who frequent the St. Lawrence, a river which habitually freezes at the bottom, to such an extent indeed that the ice sometimes drags up ship's anchors: hence the name there of "anchor ice." Lyell in "Principles of Geology," gives an interesting account of the phenomenon, and there are several references to it in Geikie's "Textbook.")—W. A. A. (If you mean the rubber tire, there is no satisfactory way of mending one. You can join with rubber solution and bind round with canvas smeared with the same, securing all firmly with string.)—CHIPS. (Have you tried the experiment? If so, what is there to explain?)—INVALID. (The cause, so far as it can be stated, is mentioned in the article.)—M. F. (You do not say at which port; but apply to Don P. Martinez del Campo, 175, Cromwell-road, S.W. He has charge of Mexican affairs. 2. You can procure the Act from the Queen's printers, East Harding-street, E.C. 3. Sixpence.)—A SHOPKEEPER. (Ventilation is the only complete remedy. There has been a good deal of discussion about it in back volumes; but so long as there is vapour to be condensed, and the air outside is colder than that inside, the windows will steam unless well ventilated. A suggested remedy is a very thin film of glycerine.)—W. CHEST. (Against the rules. The answer could be only a gratuitous advertisement, though it might be given in perfect good faith. Why not consult our advertisement columns, and read the many articles and letters on the gas engine? You should remember that the lowest-priced is not, as a rule, the cheapest article.)—ENGINEMAN. (All sorts of fancy recipes have been given in back volumes—the latest in Vol. XLI. More depends on the smith than on the solution; but plain water or salt and water ought to answer.)—CHYM. (Filter through flannel and then through animal charcoal, or adopt one of the acid processes for bleaching.)—BLACKSMITH. (You will find diagrams for a fan-blower in No. 915, p. 120, and can diminish or increase size to suit.)—W. A. L. (Yes, the brasswork must be dipped and thoroughly cleaned before the lacquer is applied. The usual dipping-acid of the shops—a mixture of nitric and sulphuric. See an article on the subject in No. 1101, and many hints, recipes, &c., in back volumes. 2. A model boiler is illustrated in same number. See also Nos. 1045, 1029, and the indices generally.)—J. P. B. (You want the pure "white" guttapercha, generally sold in sheets. If you cannot procure it in your district, send to one of the dental houses.)—TEMPUS. (For "how to make a sundial," see p. 316, No. 924, and the indices.)—J. G. (Leclanché cells are best, but data not sufficient to answer how many—perhaps three. Look under heading Electric Clocks in indices.)—IGNORANT. (Perhaps the best way to recover gold from cyanide solutions is to add hydrochloric acid slowly until no further precipitation is observed; then boil, and set aside to cool. Separate the precipitate by decantation and filtration, and add zinc filings to the liquor, which will throw down the remaining gold, which is treated as before, and added to the precipitate. The latter is then mixed with an equal weight of sulphate of potash, fused and ignited, the saline residue being dissolved out with boiling sulphuric acid. Wash with water, and the residue is pure gold. Such work ought not, however, to be done by novices on account of the poisonous fumes.)—ALEX. PAICE. (We do not think the idea would be of any great actual advantage to riders.)—B. B. (Change yours; it is preposterous to fancy that any two letters of the alphabet can become any man's special property, or that we could bear it in mind.)—WILLIAM R. WYNNE. (We prefer a drawing or tracing that we can reduce.)—REYMOND. (Correspondents should *not* put letters into the box when the office is open, but take them inside; a box is provided after office hours. We really can do nothing in the other matter; if the medical students are appropriating the copy sent for the patients, we cannot help it.)—J. FULLER. (If either communication ever reached here it was inserted or attended to. Absence of more precise particulars prevents us saying more.)

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXIX.—BY G. J. SLATER.

NOTES ON THE CHURCH ORGAN.

V.

By GEORGE ASHDOWN AUDSLEY, F.R.I.B.A.

IN the two concluding articles of this series, devoted to the consideration of the Church Organ, I touch on what may be accepted as the most important branch of my subject, namely, the arrangement and appointment of the different departments—Great, Swell, Choir, and Pedal organs. Some of the suggestions I have to submit to my readers may, on first impressions, strike them as strange and unworthy of serious thought: but I must ask them to grant the suggestions a little consideration, feeling convinced that truth will obtain in the long run. None of my ideas on this subject have been hastily arrived at; on the contrary, they are the result of nearly a quarter of a century of careful study of the organ under by no means unfavourable circumstances.

The following remarks are of very general application, that is, they are not confined to Church Organs of any special class. The methods of arrangement and appointment suggested are applicable to instruments of all sizes, from fifteen stops upwards to any desirable number.

Great Organ.

It is a prevailing and, indeed, at the present time, an almost universal impression—an impression which, in the minds of almost all organ builders and organists, appears to admit of no reasonable doubt—that the Great is the most important and most useful department of the Church Organ: and that it accordingly should contain the loudest and most assertive stops in the instrument, or, in short, that it should be able to produce as much sound as all the other departments put together. This notion has been founded upon the old German system of organ building, which obtained before any attempt was made to impart powers of expression to the instrument, or to give any part of it the means of producing a *crescendo* and *diminuendo*, without a perpetual manipulation of the stops.

I unhesitatingly affirm that the Great organ, as an *absolute* and (in the sense I here use the word) *unexpressive* department, should neither be looked upon as the most important and useful, nor be made the loudest and most assertive part of the instrument. Now, let us see if my opinion can be supported on any reasonable argument, or is based on any sensible foundation. The organ cannot be compared with any other musical instrument ever invented: as an instrument under the control of a single performer it stands alone. The only musical machine before which it assumes a secondary place is the complete grand orchestra, and it is with this complicated and animated piece of mechanism alone that any comparison can be established.

Now, for the sake of argument and illustration, let us suppose the orchestra divided into two or more sections, fairly complete in themselves; and that the destiny of one section is to produce sounds of a uniform strength or intensity at all times, without a possibility of any variation—*crescendo* or *diminuendo;* and that the other sections are permitted to exercise their full powers of musical expression. Which of the said sections would a musician decide should be the loudest and best appointed—that which he is always compelled to listen to and use at its full and unvarying power, or those which are capable of every gradation of tone and effect of light and shade? The answer is almost too obvious to require insertion here. Would he not say—"Let the *unexpressive* section be composed of those instruments which produce the purest, roundest, and quietest tones, to the uniform flow of which the ear may listen with as little fatigue as possible, if not with absolute enjoyment; and let the *expressive* sections embrace all those pungent, loud, and assertive instruments, as well as the greatest number and variety of instruments, which must be played with expression to be tolerated by the musical ear or to reach the musical sense"?

Turning now to the organ, what does the lesson of the divided orchestra teach us? Surely, that we do wrong to follow the old-world system, and make the *unexpressive* department, called the Great organ, the largest, the loudest, and the most assertive portion of the instrument. I know it is vain to expect that our organ builders of to-day will listen to such a piece of heterodoxy as that which I am here guilty of suggesting; but I am convinced, in my own mind, that my ideas will be found to be worthy of adoption in the long run. *Musicians* will, I feel sure, acknowledge the force of my proposition. Putting aside the argument based on the illustration I have ventured to draw from the divided orchestra, there is another consideration which supports my proposition—one which has a more direct bearing on the question at issue. When it is borne in mind that the Great, like all the other departments of the Church Organ, has for its chief office the accompaniment of the human voice, it must be obvious that, in its *unexpressive* nature, the tonal structure of the entire department should be characterised by a full volume of quiet, refined tone, rather than by those bellowing and screaming qualities which the majority, if not all, of the Great departments in modern organs possess. It must not be for a moment understood that I advocate the impoverishment of the Great department of the Church Organ, for such is far from my intention. I seek, rather, to increase its dignity, grandeur, and usefulness, by adapting it, in a true musical sense, to the place it occupies and the work it has to do, by imparting to it that rich refinement of tone, that volume of quiet intensity which overcome even the necessity for light and shade. To my mind the Great department of the Church Organ should be a normal organ—fundamentally and essentially an *organ*—producing sounds and combinations of sound strictly born of and peculiar to the *organ*, and unproducible by any other instrument, or any collection of instruments, under the sun.

The question now arises, How is such a Great organ to be schemed, and how should it be disposed with reference to the other and especially the *expressive* departments of the instrument?

It will be remembered that, in a previous article, I have strongly condemned the present pernicious practice of using heavy and unnecessary pressures of wind; and have advocated the universal adoption of moderate pressures, copious windage, ample scales, and a refined system of voicing for the pipe-work. All these virtues are necessary for the formation of that amiable character of tone on which the true beauty and utility of the Great organ depend. It is, perhaps, unnecessary to go into the question of wind pressure again; but I may, to save the reader the necessity of referring, reiterate one passage already written which is very much to the point:—"There can be no question that the tones produced from large-scaled and substantial metal pipes blown by a copious supply of wind at moderate pressure are in every way vastly superior to those produced from small-scaled pipes blown with high-pressure wind. For Church Organs, there can be no comparison between the two; for the tones yielded by the former are characterised by richness, volume, and great travelling power—just the qualities required for choral accompaniment—while the harsh, thin, and unimpressive tones of the latter utterly fail to satisfy the conditions of a sympathetic accompaniment." To be as practical as possible, I may at once give my opinion in favour of the adoption of $2\frac{1}{2}$in. as the maximum pressure for the Great organ. With this weight of wind, combined with a plentiful supply and proper voicing, everything desirable for this department can be arrived at.

The tonal scheme of the Great organ deserves most careful and thoughtful consideration. First of all, the proper quantity and quality of *unison tone* has to be provided by *Diapasons* and certain other stops of 8ft. pitch. In small instruments one *Open Diapason* will be sufficient, supported by two or three other unisons; but in organs of larger size two *Open Diapasons* will be necessary, for use separately and together. The first Diapason should be of large scale, yielding tones characterised by great volume and roundness—tones forming, as one might say, a cushion of sound upon which all other tones will rest in a beautiful repose. The second Diapason should be of much smaller scale, producing pure tones, characteristic of the stop, of medium power—say, midway between the strength of the first *Diapason* and that of the *Dulciana* as it is usually understood. The windage and voicing of the second *Diapason* must be essentially different to the first, so that all tendency to absorbing sympathy may be counteracted. Apart from this important consideration, the diversity presented by the two *Diapasons* will be invaluable in accompaniment. As a rule, at the present time, when two *Open Diapasons* are introduced in the Great department of a Church Organ they are far too near both in scale and strength of tone; and, accordingly, their independent utility is minimised, and a poor result is attained by their combination.

The next unison in order of importance is a covered stop, preferably of wood, of quiet, round, filling-up quality. I unhesitatingly give my vote in favour of the *Doppel-Flöte*, as it is met with in the organs built by Roosevelt. This stop mixes well and is satisfactory under all conditions. The *Doppel-Flöte* is, however, as I have previously said, unlikely to make its appearance in English organs, so we shall have to fall back upon the good oldfashioned *Stopped Diapason*, a perfectly satisfactory register for such a Great organ as I am attempting to scheme.

Difference of opinion has right to obtain with reference to the next unison to be introduced, simply because, now, circumstances alter cases. I may just remark, in organs where there is no second, small-scaled *Open Diapason* in the Great, a *Dulciana* may be added with advantage; but where the small *Diapason* is inserted, a stop of the *Gamba* species will have better effect on the general tone of the department, and be very useful in giving a diversified colouring to accompanimental music. Let the *Gamba* be voiced to produce a rich and refined rather than a pungent and rasping string-tone. The latter quality belongs to the *expressive* department of the Church Organ.

Of the stops of 4ft. pitch, the *Octave*, derived from the foundation *Open Diapason*, is, of course, the most important in the Great department. With reference to its scale, in proportion to the *parent* unison, I have, perhaps, already said enough in my third article; but may here add a few words anent its strength of tone and its true office in the tonal scheme. On referring to the particulars relating to the harmonic partial tones, given at the end of the article just alluded to, it will be seen that the first upper partial tone of a prime tone is its octave, produced by twice the number of vibrations, and, accordingly, in the organ, by a pipe half the

speaking length of that yielding the prime tone. This teaches us that the true office of the *Octave*, in the tonal scheme of the department under review, is to corroborate the first harmonic upper partial tones of the sounds produced by the unison registers; and that organ builders err when they introduce *Octaves* of too loud and assertive tones. When justly proportioned, the *Octave* materially enriches, brightens, and purifies the unison sounds, without in any way disturbing their pitch; but when of too loud intonation it imparts a screaming character to the general tone, materially aiding in upsetting the tonal balance of the organ. There is a point in every tonal scheme beyond which the harmonic sounds must not go; and he is the true artist who knows that point and never goes beyond it in his work. *The laws of musical sounds cannot be neglected or broken with impunity.* When the size of the Great department renders a second stop of 4ft. pitch desirable, it should be introduced in the form of a *Flute* of full and clear intonation, capable of enriching the general tone and of corroborating the first harmonic of the lesser *Open Diapason* and the other subordinate unison registers. More than two flue stops of this pitch are never really necessary in the Great of a Church Organ; but a third, in the form of an *Octave Dulciana* or very soft *Octave Gamba* may sometimes be introduced with advantage.

I now come to the mutation and compound registers belonging to the unison or 8ft. series. The only stops of the former class introduced in organs are the *Twelfth* and *Seventeenth* or *Tierce*.* The latter may, however, be dismissed as quite unnecessary in a separate form, notwithstanding that it was frequently introduced by the old builders in that way. The *Twelfth*, giving the second upper partial tone, when kept unobtrusive materially enriches the general tone of the department, although it is by no means indispensable in small instruments. The *Twelfth* requires the introduction of the *Fifteenth* or *Super-Octave*, which gives the third upper partial tone of the unison prime. The latter stop should always find a place in a Great department of any pretensions. In what form it should be introduced is a matter of taste; but care should be taken to have its tone subordinate to that of the *Octave* and rather more assertive than that of the *Twelfth*.

I consider one or more *Mixtures* to be absolutely necessary in the appointment of every Great organ, worthy of the name; but, as I have before remarked, the compound harmonic-corroborating stops must neither be of too large scales nor too assertive in tone. The practice of making such stops loud and screaming is decidedly fatal to that round and grand volume of tone which I hold should characterise the Great department of a true Church Organ. When a *Mixture* is of powerful intonation, it is, of course, only available with the full Great; but this is an objectionable narrowing of its utility. A soft *Mixture*, such as properly corroborates the higher upper partial tones of the unison stops, without imparting a disturbing element to their fundamental tones, will prove available with soft as well as loud combinations. Having already enlarged on the important subject of *Mixtures*, in my previous articles, it is unnecessary to say more at this point.

For Great departments of ordinary size no reed-stops beyond the *Trumpet* and its attendant octave, the *Clarion*, need be contemplated. When these are inserted, in an uninclosed condition, their tones, like those of all the other stops in the department, should be characterised by fulness and roundness rather than by a brassy and piercing quality. Their general utility and effectiveness will be much enhanced if they are inclosed in a special small swell-box. A *crescendo* on the reeds with the full Great drawn would be extremely telling and serviceable in loud accompaniment.

No stops of an essentially solo character should be inserted in the Great organ unless provision is made to impart *expression* to them. This is a principle in Church Organ apportionment which I unhesitatingly lay down and urge on the attention of all interested in organ building.

It is usually the practice to place the Great department in a front and prominent position, the Swell organ being situated behind. There is, of course, no objection to such a relative location if the entire instrument occupies a favourable place in the church, free from obstructions to the emission of its sounds; but it is unfortunately a fact that nine out of ten Church Organs are crammed into chambers, or jammed into corners and recesses totally inadequate and unsuitable. When an organ is to be placed in a chamber, or anything of the nature of a chamber, care must be taken to give the most important *expressive* department a favourable locality, so that its accompanimental office may be satisfactorily fulfilled. In such a case, the Swell must occupy the most effective position, the Great organ occupying a rear or less favourable one. The travelling and uniformly delivered volume of tone of the latter department allows it to be placed, with but little sacrifice of effect, in a position which would be destructive to the Swell organ. In some instances it may be found advisable to divide the Great organ, placing one portion in advance of, and the other behind or under, the Swell. The importance of advancing and elevating the Swell organ will be gone into in the next and concluding article of this series.

(*To be concluded.*)

* M. Cavaillé-Coll, carrying out consistently the corroboration of the harmonic upper partial tones has, in the organ in the Cathedral of Notre Dame, at Paris, introduced the "Septième" (sixth upper partial tone) in the 32ft., 16ft., and 8ft. series, the stops being respectively $4\,^4/_7$, $2\,^2/_7$, and $1\,^1/_7$ft. speaking length. This introduction is, so far as I am aware, unique.

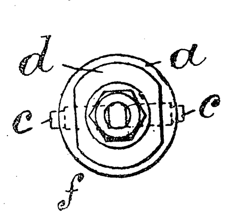

FIG. 3.

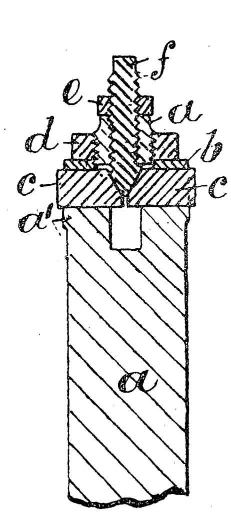

FIG. 4.

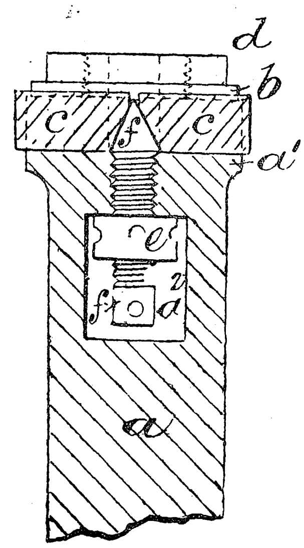

BRAMWELL'S IMPROVED BORING TOOLS.

An improved boring box, carrying various sized cutters, for use in the slotter or other machines, has been patented by Mr. S. Bramwell, of Princess-street, Stockport, the object being to make a bar in which the cutters can be readily moved or expanded to compensate for wear or for other purposes. The patentee makes the bar with a boss at one end, through which is cut a slot or slots for the cutters. In front of this slot the boss is reduced in diameter to form a projection which has a fine thread cut upon its outer surface, and it is drilled up some distance, passing through the slot with a thread cut in the hole. The cutters consist of pieces of steel fitted into the slot or slots, and these pieces are bevelled where they meet in the centre.

To secure the cutters after putting them in their places, a collar preferably somewhat smaller in diameter than the boss is screwed on to the projecting end of the boss; a washer is placed between the cutters and collar, and a set screw, with its end coned to correspond with the bevelled cutters, is screwed into the boss until its coned end bears against the bevelled ends of the cutters, so that by moving the screw further, the cutters can be expanded to the desired diameter. When this is done the collar is tightened fast up to the washer and cutters, and the set screw is then locked by a nut or nuts against the end of the boss, when the tool is ready for use. To alter the diameter, or compensate for wear, the collar is slackened and the set screw moved further into or from the cutters, when the parts are again secured and the tool is ready for use. Fig. 1 is an elevation, Fig. 2 a plan, and Fig. 3 a vertical section of a boring tool or bar made according to the invention, and Fig. 4 is a sectional view of an alternative construction. *a* is the body or shank of the boring tool or bar which is shown flat, except near the front end at a^1 where it is circular in section, the front end being reduced in diameter and formed with an external and internal screw thread. A slot is cut through the enlarged portion a^1, into which are fitted two pieces of steel *c* which form the cutters; the adjacent faces of these cutters are bevelled in opposite directions as shown in Figs. 3 and 4, and their upper edges project above the upper surface of a^1. Over the cutters is placed a thin washer *b*, and a collar *d* provided with a fine thread, which screws on to the boring bar for the purpose of securing the cutters in position. A set screw *f* with its point coned to correspond with the bevelled faces of the cutters is screwed into the front of the bar, and locked when set or adjusted by a nut *e*. To increase the diameter of the cutting edges of the cutters, to compensate for wear or for other purposes, the nut *e* and the collar *d* are slackened, so that the screw *f* may be turned in the direction necessary to force the cutters apart to the desired distance, when this has been done the collar *d* and nut *e* are again screwed up and the boring tool is ready for use. Fig. 4 represents a boring bar made of a slightly different form. In this construction the position of the set screw *f* is altered, the lock nut *e* rests in a slot a^2, formed in the bar *a*; the cutters *c* are secured in position by a screw collar *d*, the screw *f* being turned to bear against and move the cutters outward. When it is necessary to repair the cutters remove the screw *f* and screw a plug in its place into or on to the bar, *a*, and then put the bar on the centres of a

athe or grinding machine where the cutters can be turned or ground in their working position. It is evident that cutters of different sizes may be used in the same boring bar, the shank of which may be either flat as shown or round or of any suitable section.

By FRANCIS CAMPIN, C.E.

Friction.

THE term "friction" is exceedingly simple, but it cannot be disposed of by a mere definition that it is the resistance of bodies moving in contact with each other. At the hands of the mechanical scientist it demands a very careful consideration, encountered as it is at every turn, and in some form or other becoming a factor in all his calculations.

Generally a body or machine appears to be in one of two conditions—either at rest or in motion; but there is a condition which has been called that "bordering upon motion": this term, although it has found favour with some eminent mathematicians, does not seem to us sufficiently explanatory; the mass either moves or remains quiescent. We cannot conceive of an intermediate state between rest and motion, so far as actual phenomena are concerned; there may be, however, forces acting upon a body in such a way that it is not freely at rest, that is to say, some insufficient pressure may be acting upon it in a direction in which it is capable of moving if sufficient force be brought to bear upon it, as soon as the force is sufficient to balance the friction; then any additional force will cause the body to move with a velocity proportioned to the quantity of force applied in regard to the weight of the mass put in motion.

It has been found from carefully-conducted experiments that the friction from solids upon one another is, so long as the insistent pressure is not sufficient to cause abrasion, independent of the rubbing surfaces, and that it varies directly as the force pressing the surfaces together, varying also with the nature of the surfaces in contact. It is not affected by the velocity of the movement. When unguents are used, the friction depends upon the nature of the unguent alone if the pressure per square inch on the surfaces is not too great to allow a complete layer of the unguent to remain between them; if, however, the unguent is pressed out the friction will increase, the condition approaching that of two surfaces rubbing together in immediate contact. The pressure actually necessary to cause the motion of one surface upon another, divided by the pressure acting upon the surfaces in contact, is called the coefficient of friction.

The amount of this coefficient has been said to be greater for the friction of rest than for the friction of motion; but when the body is at rest there cannot be any friction. It would seem that this distinction has been suggested by the fact that a greater effort is required to start a mass than to keep it moving; but this is at once accounted for by the fact that in addition to the force to balance the friction, a force must be applied to overcome the inertia of the body, and supply it with the accumulated force corresponding to its velocity.

In Fig. 6 let $a\,b$ represent the surface of an immovable solid body, and let g represent another surface in contact with it, and acted upon by the pressure P; so long as the pressure P acts upon the surfaces at right angles to their plane of contact, it will have no tendency to slide the upper one upon the lower; but if the force be inclined such a tendency will at once arise to that effect, and should the inclination be continued a position P′ will be found when the frictional resistance of the surfaces will be equalled; then the angle PgP′ is termed the limiting angle of resistance, and if g be put in motion it will continue to move with a uniform velocity, and if it is stopped it will remain at rest.

Continue the direction of the force P until it meets the surface $a\,b$ in the point c, and produce P′c to e, making $c\,e$ represent the intensity of the force P′. This force may now, by the parallelogram of pressures, be resolved into two component resistances, one being the resistance of the surface $a\,b$ at right angles to itself, and the other the frictional resistance

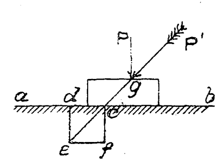

FIG 6

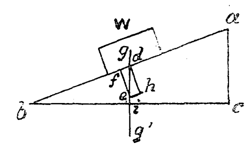

FIG 7

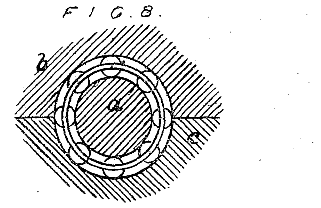

FIG. 8.

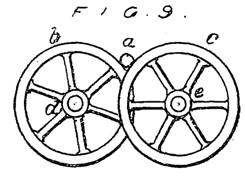

FIG. 9.

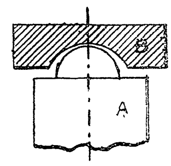

FIG 10.

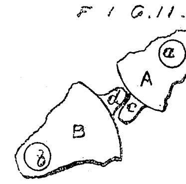

FIG. 11.

parallel to $a\,b$; complete the parallelogram $c\,f\,e\,d$, then will the normal pressure against $a\,b$ be represented by $c\,f$, and the frictional resistance between the surfaces in contact will be represented by $c\,d$ or $e\,f$, for $c\,d$ and $e\,f$, being opposite sides of a parallelogram, are equal.

The force then necessary to equal the frictional resistance due to a pressure $c\,f$ is measured by $f\,e$; therefore $\frac{f\,e}{c\,f}$ = the coefficient of friction for the material which is under examination.

Now it is to be observed that whatever the actual intensity of the force P′ may be, motion will ensue on its passing the limiting angle of resistance.

In Fig. 7, let $a\,b$ represent the surface of an inclined plane upon which is a body W; let $b\,c$ be a horizontal, and $c\,a$ a vertical line; $c\,a$ will be at right angles to $b\,c$.

Let the elevation of $a\,b$ be such that the mass W is on the point of slipping from its centre of gravity g, let fall the vertical line $g\,g'$ cutting $a\,b$ in the point d, mark off $d\,e$ equal to the weight W, and complete the parallelogram $d\,h\,e\,f$; then $d\,h$ will represent the normal pressure on $a\,b$, and $d\,f$ or $e\,h$ the force parallel to $a\,b$ $\frac{e\,h}{d\,h}$ = coefficient of friction $= \frac{a\,c}{c\,b}$, because, $g\,g'$ being drawn vertical, is parallel to $c\,a$ and at right angles to $b\,c$, which it cuts in the point i; $d\,h$ and $f\,e$ are drawn normal to $a\,b$, therefore $d\,h\,e$ is a right angle, and the remaining angles $e\,d\,h$, $d\,e\,h$ together equal to a right angle. Because $d\,i\,b$ is a right angle, the remaining angles $i\,b\,d$, $b\,d\,i$ are together equal to a right angle, and therefore equal to the angle $e\,d\,h$ $d\,e\,h$ together; but $b\,d\,h$ is a right angle, and is equal to the two angles $b\,d\,i$, $e\,d\,h$ together; therefore, deducting the common angle $b\,d\,i$, the remaining angle $i\,b\,d$ is equal to the remaining angle $e\,d\,h$; but if two angles of one triangle are equal to two angles of another triangle, the third or remaining angles are equal, and the triangles are similar; and $e\,d\,h$ is similar to $d\,b\,i$. It may also be shown that the triangles $d\,b\,i$ and $a\,b\,c$ are similar for the lines $d\,i$ and $a\,c$ being parallel, the angles at d and i will be equal to the angles at a and c respectively, and the angle at b is common; hence the triangles $a\,b\,c$ and $e\,d\,h$ are similar, and $\frac{a\,c}{c\,b} = \frac{e\,h}{d\,h}$ = the coefficient of friction.

When a body rolls upon another there is no friction, as the rolling motion consists in placing the parts normally in contact, and again lifting them away, and between this and the friction of sliding contact innumerable modifications of the frictional resistance may be obtained.

Let us consider what is the work done in overcoming friction, and that will lead us to find methods of diminishing it. In the first place, for a given material the coefficient of friction is constant—let it be represented by F: then if S be the distance through which the moving body, whose weight is W, passes in a given time the work done will be W × F × S. Let this be supposed to apply to a mass of iron weighing one ton (2,240lb.) drawn upon a surface of iron through a distance of 1,000ft.; the coefficient of friction for iron is 0·25; the work done will be = W × F × S = 2240 × 0·25 × 1000 = 560,000ft.-lb.

Now, instead of sliding the load, let it be mounted on wheels 3ft. in diameter, fitted with axles 2in. in diameter, and let it be run upon a perfectly level road. It is evident that the distance through which the friction of the rubbing surfaces is overcome will be much reduced, for while the moving mass passes over a length equal to the periphery of the wheel, the rubbing surfaces only pass through a distance equal to the periphery of the axle, and as the circumferences of circles are in simple ratio to their diameters, the work in the latter case will be to that in the former as 2 to 36, or one-eighteenth, the loss by friction in the first case being one-quarter the weight would be at the rate of 560lb. per ton of load, but in the latter 31·1lb. per ton. If unguents are used the coefficient of friction will be about 0·08, or for the sliding mass 179·2lb. per ton; but for the load on wheels the loss would be 9·95lb. per ton.

About this matter there must be no confusion. It is usual to say the frictional resistance of a train is 10lb. per ton, or whatever it may be for the particular class of rolling stock; but this must not be looked upon as a co-efficient of *friction*, as it involves the coefficient of friction multiplied by the distance through which the rubbing surfaces pass, and divided by the distance through which the whole mass passes.

If perfectly cylindrical rollers are placed on a true surface and support a plate having a perfectly true under surface, then there would be no friction; but the plan would not be practicable, because the rollers themselves would run out from under the surface they are required to support. A system of rollers may, however, be interposed between the neck or "journal" of a shaft, and the bearings by which it is supported as shown in the section Fig. 8; a is a section of the shaft to be supported, b and c being the top and bottom bearings, between the shaft, and the bearings are shown eight small rollers, which are kept at their proper distances apart by means of two rings having holes in them, through which the centre pins of the rollers pass; the whole friction will be that due to the weight of these rings and any pressure caused by the tendency of one roller to overtake another by slipping or inequalities of workmanship.

Another method of reducing the friction of revolving shafts which is applicable to very delicate scientific apparatus is shown at Fig. 9. a is the shaft to be supported; at each end it rests upon two large wheels, b c, placed close, one behind the other, and themselves supported on axles d e, and as such contrivances are only used for very delicate apparatus, the ends of these axles may be turned down to exceedingly minute diameters, so that the effect of frictional resistance upon a becomes practically inappreciable. It has been stated that the *coefficient* of friction is not in any way affected by variations in the amount of surfaces of contact, and this is perfectly true so long as the pressure upon those surfaces is not sufficient to approach abrasion; but, notwithstanding this, it can be shown that an increase of surface may materially in some cases increase the loss of work by friction.

It must be remembered that the velocity does not affect the coefficient of friction; but the work absorbed by it is dependent on the distance passed over by the rubbing surfaces.

We are now going to instance the case of a vertical shaft supported upon an end bearing or step, such as occurs with the shaft of a

turbine, or with the bearings of a certain description of turn-table for locomotive engines; only, in this case, the vertical spindle is fixed, and the revolving bearing rests upon its top.

If we have a plain, flat bearing it is evident that the distance passed over by the rubbing surfaces will be measured by the circumference of a circle having a radius one-half of the external radius of the bearing surface, so that the loss of work by friction will vary directly as the radius of the end of the shaft; it is therefore incumbent upon us to keep this as small as possible, and in those turn-tables to which we have referred the minimum must be reached. The arrangement is shown in Figure 10. A is an upright pillar carrying at its top a steel paraboloid, upon which rests a steel cup, B, firmly fastened to the superstructure of the turn-table. The interior surface of the cup is of a larger radius than is the exterior surface of the bearing piece, so that the actual bearing surface is that due to the change of form by compression under the superincumbent load. These turn-tables consist of two girders attached at their centres to the frame carried by the cup B, and upon them are rails on which the engine to be turned is run. At each end of the girders are two wheels, under which are fixed rails, running in a circle round the turn-table pit. These wheels are to take the weight of the engine while it is being run on to the table, and are so proportioned that on the balancing of the engine in the centre of the table they hang suspended just clear of the rails; one man can then, without difficulty, push round a table with a 60-ton engine upon it.

In certain kinds of machinery the value of the limiting angle of resistance is a most important factor indicating the forms necessary to be given to the contact surfaces of driving and driven elements, such as toothed wheels, canes, screws, and other elements to be fully treated of subsequently.

In Fig. 11, let A represent a driving element, mounted on an axis, *a*, and carrying a projection, *c*, which, by pressing against the projection *d*, which is part of the element B, mounted on the axis *b*, will cause B to rotate when A is put in motion. Now, it is evident that to obtain satisfactory results the surfaces of *c* and *d* should be so formed that their motion one upon the other will be a pure rolling motion; otherwise there will be friction, which means both loss of power and rapid wearing away of material.

In order that there may be no friction, the direction of the pressure at the point of contact of the driving and driven surfaces must always be at right-angles to those surfaces, and the more the direction of that pressure deviates from this position the greater will be the loss by friction.

(*To be continued.*)

THE PATENT "GREENSHIELD" BRUSH-HOLDER.

THIS tool, which seems to us likely in no small degree to facilitate the work of painters, is designed to carry an ordinary paint brush of any size on the end of a wooden stick or long arm, for painting or cleaning the sides of ships and other inaccessible places. Fig. 2 shows the brush in one of its extreme positions. It is adjustable to any point between the position shown and a horizontal one. A is a taper socket for holding the paint brush E. B is a thumb nut for closing socket A to grip the brush after it has been pushed in. C is a thumb nut for adjusting angle of brush in slot S to suit the work to be done. D is an ordinary taper socket with nail or screw for holding stick or long arm F. F is the long arm or stick, shown broken off, any length as desired. A special form of socket A may be provided for stock brushes, &c., as may be required. The advantages are that, as may readily be imagined, it effects a great saving in time over the usual process of tying the brush on to a stick; the brush is readily adjustable to any angle to suit its work, effecting an economy in time, paint, and brushes; and, lastly, simplicity, durability, and lightness are secured. There are no springs or anything that can get out of order. The price is remarkably low.

OVER AND UNDER EXPOSURE.

IF upon applying the developing solution the image takes a very long time to appear, it may be concluded that either a too brief exposure has been given or that the developer is too weak. If the former is the case, it will be signified by the high lights eventually acquiring vigour, the deep shadows being either exceedingly tardy in appearing or failing to come out at all. If, on the contrary, there be no such wide distinction between the lights and shadows, but only a general disinclination of any image to appear, the presumption is that the fault lies with the developer. The remedy in this latter case is to increase the proportion of the alkali, which treatment will never fail in bringing out the details. As we have said before, it is not wise to add so much as to render the development too rapid. Again, it happens with many brands of plates that the presence of alkali in such a proportion as would effect a very quick development may fog or veil the shadows. This is prevented by the addition of two or three drops of a fifteen grain solution (*i.e.* fifteen grains to an ounce of water) of bromide of potassium or bromide of ammonium, the function of which is to prevent any abnormal deposit on the shadows, or to keep them clean. But owing to the retarding influence of the bromide it must be used sparingly. However, it permits of the employment of a larger amount of alkali than it would be safe to introduce into the developer without such a check upon its energy. It is not quite easy to say precisely how much ought to be added, because of the diversity in character of commercial plates, the best treatment for one brand not being necessarily that for another. There are some plates which require no bromide at all, while others are very liable to fog unless a liberal proportion is present.

Should the image make its appearance with too much equality all over, the shadows coming simultaneously with the lights, it may be taken as evidence of over-exposure. In this case it is necessary to act promptly, and at once to pour the developer back into the graduate or cup, and add to the solution a liberal dose of bromide, say four drops or more, according to the circumstances of the case, and having stirred the solution so as to mix it well up return it to the plate. The object of this is to retard the action of the developer upon the shadows, which are thus held in check, while the developing action goes on in the high lights. Under this altered condition of the developer the plate may be subjected to its action for a prolonged period without danger of the shadows becoming fogged. If it is known beforehand, or very strongly suspected, that the plate has received much too long an exposure, then will it be wise to introduce two or three drops of the bromide solution along with the pyrogallic acid previous to adding any alkali at all, as this will in some measure ameliorate the effect of over-exposure, while the alkali may also have its action checked by a similar addition of bromide.

What has been here said applies, of course, to pyrogallic development, and it can be readily inferred that by an intelligent adjustment of the component parts of the developer, or perhaps, more correctly speaking, of the alkali and the bromide, a considerable latitude in the exposure is permissible. In all photographic operations development, more than any other, requires the exercise of judgment. Almost everything else can be effected by a hard-and-fast rule, but development is amenable to the intelligence of the operator, an intelligence that must be exercised in the case of every individual plate.

In ferrous-oxalate development there is not the same degree of latitude as in that by pyrogallic acid, although in cases of over-exposure the latent or even partially developed image is amenable to the retarding influence of bromide, a few drops of which may, especially at the initial stage of development, be added with marked advantage.

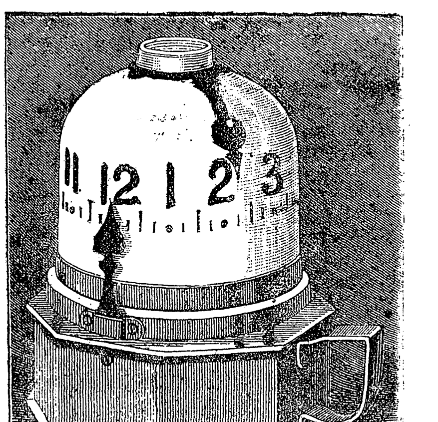
Another factor in facility of development is weakening the developer by the addition of water. But concerning the effects of this we shall have occasion to speak more fully when we come to consider the best circumstances under which to develop snap shutter or instantaneous exposures.

The darkening of the pyro developer, which not unfrequently becomes of a muddy-looking nature after remaining on the plate for a few minutes, may be prevented by sulphite of soda. One of the best ways to employ this salt is to saturate with it the water in which the pyrogallic acid is dissolved. Provided this is done, an aqueous solution of the acid may be made which will keep good for a long time, whereas if it be dissolved in water alone without the sulphite it will decompose with so great a degree of rapidity as to render its preparation in this way a loss.

There are several other additions which may be made to the solution which will prevent the pyro from decomposing, but the consensus of opinion points to sulphite of soda as being the best at present known. It will prove highly educational to the beginner if he will develop a plate without such addition, and note the state in which he finds the developer at its close, and afterwards go through the same operation with a second plate, a liberal proportion of sulphite being mixed with the developer. So clear will it remain in the latter case, compared with the muddiness of the former, that he will be tempted to use it over again on the succeeding plates, which may, in many instances, be done with advantage.—*British Journal of Photography.*

ILLUMINATED CLOCK.

THE accompanying engraving represents a simple and practical device which embodies a day, night, and medicine clock, and which also provides a night light. Within the base is placed a clock mechanism, the hour spindle of which



passes up through the centre of the top and is secured to a dished plate, which is by this means revolved once in twelve hours. Resting upon the plate, and, of course, turning with it, is a dome-shaped globe of white glass, having the hours and quarter divisions marked distinctly in a circle upon

its exterior. Secured to one side of the base is a pointer which extends to the row of figures. It is evident that as the globes revolves, the time will be indicated by the pointer. Within the globe is placed a small lamp, which serves to render the figures and pointer plainly visible, so that the time may be read at night, and also to illuminate the room with a soft and yet sufficient light. Adapted to rest on the top of the globe is a second pointer, which may be placed at any desired distance in advance of the stationary pointer. This will be found of value in the sick room, as, when giving medicines, the second pointer can be placed the required interval between doses — say two hours—in advance of the other, the lapse of the time being noted when the pointers are together. By thus combining a lamp and clock, a most convenient and valuable article is produced. These clocks are manufactured by the W. C. Vosburgh Manufacturing Company (Limited), of 418, Fulton-street, Brooklyn, N. Y.—*Scientific American.*

NOTES ON THE PROCESS OF POLISHING AND FIGURING 18in. GLASS SPECULA BY HAND, AND EXPERIMENTS WITH FLAT SURFACES.*

By H. F. MADSEN.

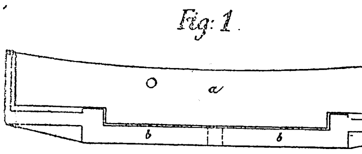
THE full text of the paper of which we gave an abstract on p. 58 having been received from the author, we give it complete, with the diagrams:—

So much has been written upon the production of glass reflectors for use in astronomical observations, and so many of these being in use at the present time, any improvements in their construction would be difficult, if not impossible, to attempt; still, as the method which I have followed is not altogether the usual one, and as I am not aware that any mirrors of the size under discussion have been attempted by hand, I have thought it probable that certain notes taken down by me during my experiments might not be altogether void of interest to some of the members of this society.

It is now more than four years ago since I first began polishing specula-flats, &c., with other optical experiments. During this period several mirrors from 7in. to 18in. diameter have been completed with gradually increasing success in the result. As the rough castings for the 18in. mirrors were somewhat expensive, these have been refined and repolished several times to gain practical information in their construction. They were imported from Chance Bros., Birmingham, and when polished, were found to have been well annealed.

A piece of plate-glass 10in. diameter was cemented to the back of each mirror to suit its intended cell or mounting, and the weight of the whole speculum when finished was about 70lb. (Fig. 1). In producing these specula the first

Fig: 1.



a, Speculum; *b*, Iron Cell.

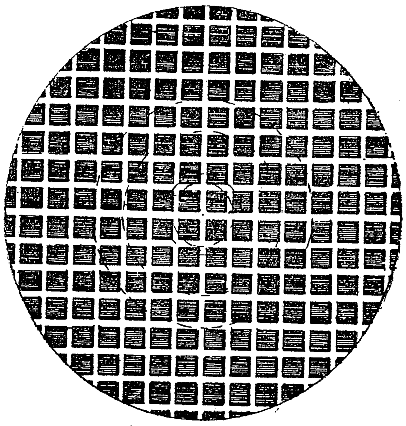
thing to consider is naturally the convex tool with which they are ground to the proper curvature; and my first attempt was made by procuring two flat discs of glass of the same size, and grinding them together with emery and sand, the intended speculum occupying the uppermost position until they had attained the desired form; it being well known that two flat discs when ground together will form themselves into spherical surfaces, the overhanging part of the top one producing convexity in the one underneath.

My succeeding trial was made by the usual iron tool turned to approximate curvature in a lathe; but it was found that two of these had to be ground together for a considerable time before they became of a true spherical form; and knowing that the coefficient of expansion of iron was 0·000012, that of glass only 0·000008, and that in both cases the surfaces were very sensitive to small variations in temperature (as illustrated hereafter by my flat surfaces), I formed the opinion that a truer surface could be produced by having the tool made of the same material as the intended reflector, and, therefore, in producing the two larger specula under consideration, I reverted to my former process.

Three plates of rough glass, 1in. thick and 18½in. diameter, were ground together to fit one another, and then cemented so as to form a firm and solid block.

To produce the proper convexity in so large a size in the usual manner would occupy a considerable time, and require a great amount of labour; yet such a form would be easily given to it by the machinery used by plate-glass grinders. I had the tool made of about one-quarter more convexity than the required concavity of the speculum, and the latter having been partly hollowed out by the

FIG. 2.

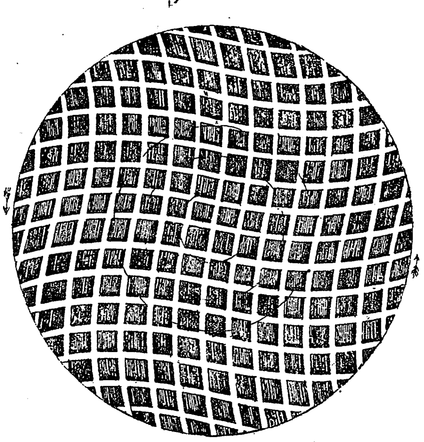


use of a leaden weight and rough emery, the two (tool and glass) having been ground together, soon formed themselves into perfect spherical surfaces, and very nearly of the proper curvature.

Where many specula are to be produced upon the same tool, iron may be preferable on account of its surface becoming extremely hard; but I have with one of glass ground or rather refined the speculum during three hours, without producing so much as 1in. alteration in the focal length.

During the course of my earlier attempts with

Fig: 3.



Radius of Curves equal to Radius of Circle.

smaller glasses, much time was lost in the polishing, the smoothing process not having been sufficiently carried out with the finest grade of emery; but with the two under consideration to-night this was guarded against, and no polishing was begun until the mirror was bright enough to reflect the image of the sun at an almost perpendicular incidence.

In one instance, to ascertain the exact form of the surface given to the speculum by the glass tool, I endeavoured to render it thereby reflective enough without polishing for a preliminary examination at the centre of curvature. In this I did not quite succeed, but with 5m. polishing it reflected the light from a very small pinhole, and when thus examined I was delighted to find that it presented a true and regular surface, slightly inclining from the spherical towards the spheroidal form, and that irregularities of more than $\frac{1}{30000}$in. (probably much less) had no existence.

This proved beyond doubt that the class of tool I had used left nothing to be desired. The speculum having, then, at this stage of the process an absolutely true curve, the polishing was proceeded with in the usual manner with rouge upon pitch (the speculum being uppermost), so well described by the late Dr. Draper, Mr. Wassell (ENGLISH MECHANIC), and others, until no emery holes or scratches could be seen by looking in an oblique direction at the reflected image of the sun near the focus.

In all cases, however, that I have seen described, the pitch polisher has been directed to be graduated into squares as in Fig. 2, where it will be seen that the circles described from the centre will all intersect the squares at nearly the same angle. I have read that Lord Rosse, Dr. Draper, and others, had to add an extra motion (side motion) to the speculum to avoid concentric grooves or rings; but it seems to me that a polisher graduated as shown would naturally produce such, if the glass continually moved in the same track. I also found that when the pitch was very hard, the glass would move more easily along the grooves than in any other direction; and, therefore, I graduated mine as shown (Fig. 3), where it will be found that these defects are obliterated, and I may state that I have, without side motion, polished (by hand) for hours continually without producing as much as a trace of a ring.

The polishing for this size of speculum (by hand) usually occupies about seven or eight hours, but in the one before us to-night it was accomplished in five hours thirty minutes; after which it was tested and found to have retained its original shape, slightly inclined to the spheroid. (This, however, may have been changed often during the polishing.)

As shown hereafter in my method of figuring, or in converting the surface into a paraboloid of revolution, the spheroidal form would be as good to start from as spherical; but it must not be forgotten that the spherical form is the only state in which almost infinitesimal irregularities can be observed, except by varying the distance of the luminous point. In fact, so delicate is the Foucault test of a true spherical surface at the centre of curvature, that variations of 0·000001in. (as is proved hereafter) can be noticed. Supposing, however, that a true spherical surface has been obtained, the most delicate part of the process commences—viz., to change it into a paraboloid of revolution, or what is the same, to correct the spherical aberration.

Some opticians have attained great success in this operation, and there can be no doubt that a similar effect can be produced more or less favourably in several ways. I will here enumerate some of them:

1. By making the polisher a little larger than the speculum (Herschel), or by making it of an elliptical form, axis as 10 to 9 (Short's process). Without doubt this will lengthen the outside rays, but the regularity of the curve from the centre seems to me doubtful.
2. By gradually lengthening the strokes (Dr. Draper); not tried.
3. By raising the temperature of both glass and polisher, and before the pitch becomes of its usual hardness to use a few long strokes (half-strokes), afterwards gradually decreasing them to nothing. This I have tried with partial success.
4. By local polishing, as adopted by Lassell; perhaps the one now mostly used, and the process by which the greatest success has been obtained. Its defect is that small irregularities are almost impossible to avoid.
5. By graduating the pitch polisher, which, in my experiments, seems to be the process most certain of success; yet in large surfaces, where a considerable amount of correction is to be performed, great care is necessary to avoid it running into an irregular curve.

As in this process the main point to be considered is the correct system of graduations to be used, I began by inquiring into the form of the solid interposed between the sphere and paraboloid of the same curvature at the point of contact, seeking thus to combine theory and practice.

The general equation to this solid becomes complicated; but as it was only required to know the variation in the thickness of a section from centre to edge by combining the equations of the circle and parabola, I deduced an approximate expression (correct for the usual shallow curves to eight places of decimals) thus:—

Equation to parabola origin A is—

$$x^1 = \frac{(y^1)^2}{4f} = \frac{(y^1)}{2r.}$$

" circle— $x = r - \sqrt{r^2 - y^2}$

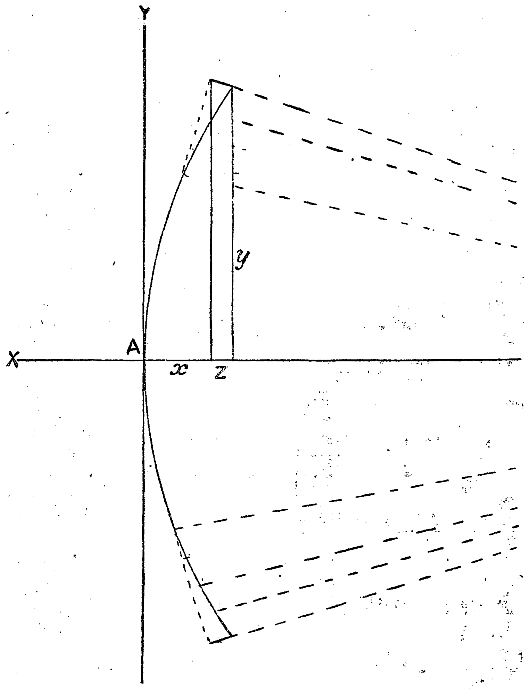
which, being expressed in series, is—

$$x = \frac{y^2}{2r} + \frac{y^4}{8r^3} + \frac{y^6}{16r^6}\ldots\ldots$$

Let now $y^1 = y$, and neglecting higher powers of y than the fourth, we have by subtraction $(x - x^1)$ $= z$ equal to thickness for any value of $y = \frac{y^4}{8r^3}$ and supposing r constant, it is seen that such varies as fourth power of semi-diameter.

Let now z be calculated for intervals of 1in. in the length of y with radius $(r) = 320$in. as in the speculum under consideration, and as has been done in the subjoined table, the section will be

* A paper read before the Royal Society of N.S.W., July 7, 1886.



y in ins.	$\frac{y^4}{8r^3}$	$\frac{y^4}{8r^3}$ in millionth parts of an inch.	$\frac{y^2}{r}$ aberration at centre.	Approx. fractions.
1	0·000000025	$\frac{1}{250}$	0·003	$\frac{1}{320}$
2	0·00000016	$\frac{1}{16}$	0·0125	$\frac{1}{80}$
3	0·0000003	$\frac{1}{3}$	0·0281	$\frac{1}{36}$
4	0·000001	1	0·05	$\frac{1}{20}$
5	0·00000244	$2\frac{1}{2}$	0·078	$\frac{1}{13}$
6	0·00000496	5	0·1125	$\frac{1}{9}$
7	0·00000916	9	0·153	$\frac{10}{65}$
8	0·0000156	$15\frac{1}{2}$	0·2000	$\frac{1}{5}$
9	0·000025	25	0·2531	$\frac{1}{4}$

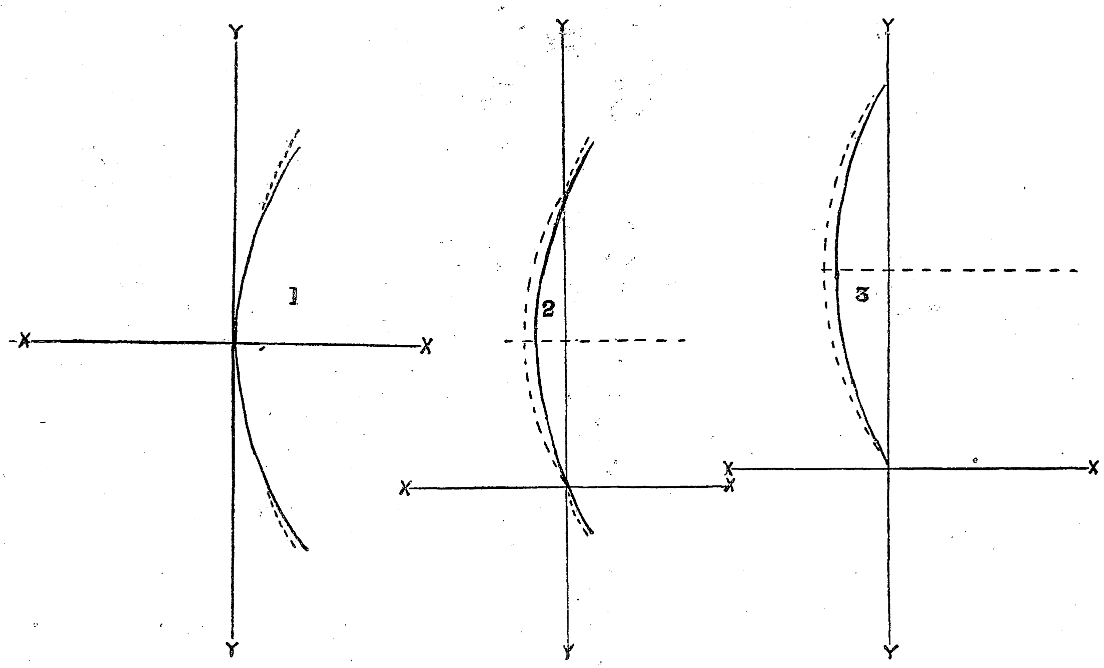
represented by the above diagram (in which the solid line represents a section of the spherical surface, and the dotted line the corresponding parabola).

In this table the first column gives the length from centre of semi-diameter (y) in inches; the second and third, the corresponding magnitude of ($x - x^1$) or z, or the amount of abrasion required to change the section of a sphere into that of a paraboloid of revolution, and the fourth and fifth columns, the longitudinal aberration of the latter curve existing at the centre of its main or rather least curvature; calculated from the formula $\frac{y^2}{r}$ (approximately), and this is known to be four times the amount the same speculum would show (if spherical) in the telescope at its focus.

Although in this case the relative length of focus to diameter is not by any means an unusually long one, yet, by examining this table, some startling truths are revealed.

In the first place, it seems wonderful that the deviation in a ray of light should become perceptible by the variation in the reflecting surface of one-millionth part of an inch, which is actually the case.

At 4in. from the centre the distance from the two curves is only that amount, and yet this produces $\frac{1}{20}$in. longitudinal aberration at the centre of



curvature, which, under favourable circumstances, can easily be perceived; but, on the other hand, as this small variation might be produced by three strokes of the polisher, or by the smallest irregularity in temperature, it shows that practically the curve for the central 8in. should be spherical, and that, with mirrors having very shallow curves as 12in. diameter to 20ft. focus, such a form is as good if not better than any other.

In the above calculations the point of contact (also origin of co-ordinates) of the two curves has been supposed to be at the extremity of their axes of revolution; but, as in the paraboloid the curvature increases continuously from centre to edge in the given ratio, other points might be selected either at the edge or at intermediate places, and the three cases would be as shown in 1, 2, and 3.

(*To be concluded.*)

MIRROR - PAINTING.

THE first step in mirror-painting is to decide upon the design. If this is but a copy, take a tracing of it off upon ordinary tracing-paper; if it is to be an original, arrange the selected flowers in a good position, exclude all but the north light, and draw them to size upon drawing-paper, and tint them with water-colours to indicate their colouring, where the deepest shadows should fall, and where the reflected lights thrown from a transparent leaf or petal on to another part of the design appear. By thus obtaining permanent directions as to the management of these important details, the worker can rearrange the real flowers daily, so that the same effect is produced throughout the painting, and she will not be worried by finding that, at a second sitting, all her flowers that were in full shadow are now in light Take a tracing of the chief outlines of this sketch, rub the glass quite clean with a chamois leather, and lay the tracing-paper upon it, with a sheet of red carbonised paper between the glass and the paper; with the point of a hard pencil go over the traced lines steadily, and remove both papers, when the outline will be clearly seen on the glass. Mix a little flake-white with medium, add to it a colour that matches one of the flower tints, and secure their outlines by going over them with this colour in a fine brush. Match one of the shades of the leaves, and work in leaves and stems with the green mixture, but work in the first painting of the flowers before the outline has dried and before the leaf-outline is secured. Work in the deepest shadows first, then the half-tints, and lastly the high lights. Mix all these shades on the palette with the medium, apply them with an even hand, and soften and run their edges into each other with a clean and dry brush. Use as little paint as possible; put it on with but few touches, and be careful that the outline of each petal is clear and not ragged-looking. Having toned in the chief petals, work at the under petals, and imitate the transparent look of the natural under part of a petal through which the light is passing by a soft gradation from dark to light, making the tone lighter than nature, and running the paint together with a fitch brush, whose hairs are softer than sables. While the paint is drying, outline the leaves and fill in their shadows, medium, reflected, and high lights, and leave the work until dry, when re-paint the flowers and leaves, softening the

colour, but bringing it up to its natural tones, deepening such shadows as lie close to the high or reflected lights, and blending together crude masses of colouring. In the final painting add the peculiar markings of the flowers, vein the leaves, and lightly apply washes of transparent colour where the colours require warming up or toning down.—*Lady's World.*

PHOTOGRAPHIC LENSES.—II.*

By J. TRAILL TAYLOR.

WIDE-ANGLE, non-distorting objectives are a great power in the hands of a photographer who knows how to use them aright. Among the earliest of these was the American globe lens, so termed from the outer surfaces forming part of a globe or sphere. From the example now shown, it will be observed that each lens (the combination is symmetrical) is formed of a meniscus crown with the shorter radius from the optical centre, cemented to a concavo-convex flint. The construction of this lens favoured the formation of a flare spot, or ghost, in the centre of a picture, which would have disappeared had the maker departed from his globular idea, and brought the lenses a little closer together.

In 1864, Ross took the matter up and brought out a doublet free from the shortcomings of the globe. It was unsymmetrical in internal structure, being composed of a bi-convex and a bi-concave cemented front, and a concavo-convex and meniscus back combination. The lighter element, as you see, is to the outside of the front and the denser element to the outside of the back. Soon after this, Zentmayer introduced a ratio lens, one in which the front and back elements were of dissimilar diameter and focus, the diaphragm being placed in the optical not the mechanical centre. The objective was composed of two single or non-achromatised meniscus lenses of very deep curvature, and included a very wide angle. A feature by which it was distinguished consisted in a series of lenses of different foci all screwing into one mount under such circumstances as to retain the diaphragm in the correct position for all of them. This was improved upon by Dallmeyer, who made a wide-angle rectilinear lens in which the lenses are each achromatised.

A wide-angle lens much used in America, made by Morrison, consists of a very deep achromatic front lens and a single or non-achromatic crown meniscus as a back lens, of rather flatter form than the front. This, presumably owing to slight over-correction of the front, aided by the well-known adaptability of the deep meniscus form, defines sharply over an extended field.

In 1866, Steinheil introduced a lens formed of two cemented combinations, adapted for covering a moderately large field with an aperture of a seventh of its focus. Instead of forming it of flint and crown glass, which would not admit of such an aperture being employed, he used two kinds of flint glass, one possessing a higher index of refraction and dispersion than the other. From their wide aperture they were designated *aplanats.*

Numerous makers took the matter up, some by servile imitation, others by making departures more or less slight. This objective, which is more or less good according to the skill of the optician by whom it is made, is, for all-round work, one of the greatest possible value, for in a fairly good light it acts as a portrait and group lens; it is sufficiently rapid to enable the photographer to secure horses, even railway trains, in motion; it is orthoscopic, or rectilinear, hence can be employed for copying, and provided care in this respect has been bestowed upon its construction, it serves as a landscape lens, in giving no ghost or flare. But it is unfortunate that some makers, in their efforts to render it otherwise perfect, do not realise the importance of providing against the defect named. The lenses are separated so far as to hit a happy medium between flatness of field and astigmatism, and this is not unfrequently attended with flare. I have invariably found that this defect may be cured by bringing the lenses a little closer together in the mount. Even so little as the width of two threads of the screw has served to dissipate the flare spot, which in many cases consists of an image of the diaphragm, which has a relation of conjugate focus to the back lens when internal reflections form a factor in its production, although it is sometimes occasioned by reflections from the front lens.

In the course of the discussion which followed Mr. J. Mayall, jun., said he noticed, in the early part of the paper, a reference to the term aplanatism, but it appeared to him that the expression was perfectly well defined by the classical writers on optics. Coddington, the well-known inventor of the lens which bore his name, in a treatise on the "Reflection and Refraction of Light" in 1829, defined it as meaning freedom from spherical aberration; and that definition was adopted by Sir John Herschel in his famous treatise on "Light" in the "Encyclopædia Metropolitana." He could not but think that if in the description of photographic lenses it was used in any different sense—for instance, as Mr. Taylor employed it, as meaning the angular aperture of a lens—it was an extraordinary misapplication of the term. Of course he did not attribute the origination of that idea to Mr. Taylor, because it had been more or less used in popular treatises on photographic lenses, and even in Monkhoven's work on photographic optics. Mr. Taylor had referred to a great number of lenses of the old type, many of which were quite obsolete and of no use whatever. On the other hand, he had touched on certain lenses recognised throughout Europe, as showing the highest point of excellence which had yet been reached. He took it that since the application of the dry-plate process, the old Petzval form, in which an extraordinary aperture was given in relation to the focal length, was practically useless, and everyone now used lenses having much less aperature, but where the aplanatism was infinitely more perfect. Reference had been made to the lenses made by Steinheil, in which flint glass was used for the external lenses. That point was taken up by a distinguished mathematician in Paris, some ten years ago, M. Prazmowski, the partner of Hartnack, the eminent microscope optician, and it led him not only to utilising flint glass for the external lenses, but also to combining different kinds of flint glass, and he had a very distinct aim, viz., to get rid, in portrait lenses, of the separation in the back combination, which he obtained by using two different kinds of flint glass for each combination, and thus produced a lens with a very short focus, with each combination cemented, so that the reflection given by the surfaces being exposed to the air was got rid of. One of the first lenses thus made, was made for him, as the result of a long discussion with Prazmowski, and having brought it to London, he thought it would be interesting to Mr. Dallmeyer to see it. He remained about an hour while he tested it; but he was surprised to find that, although he was known to have considerable technical knowledge, he had not the slightest conception of the nature of the combination, how the problem of getting rid of the separation of the back lenses was solved, or that the lenses were constructed wholly of different kinds of flint glass, no crown being used. He must confess that even that was now a thing of the past, because it dealt with lenses of the Petzval construction, with great aperture and short focal length, which might now practically be looked upon as out of date. With regard to new kinds of glass for use in lenses, Mr. Taylor seemed to think it was too soon to deal with that question, but he should like to say a word or two on the optics of the future, as they might be developed by new kinds of glass which had lately come into the market. It was perfectly well known in the microscopical world that, some time ago, one of the most distinguished mathematicians in Europe, who had paid special attention to practical optics, Professor Abbe, of Jena, and his friend, Dr. Schott, had worked out an immense number of experiments with the purpose of providing new of lines in the spectrum than had been hitherto kinds of glass which would combine a greater number combined. Of course, that in itself was old, some of our most able mathematicians, such as Professor Stokes, Mr. Grubb, and the late Dr. Robinson, having applied themselves to the problem, any time during the last thirty years; but, unfortunately, their experiments had not ended in any practical result. In this case, however, Prof. Abbe being the theorist, and Dr. Schott a practical man, there was a combination which led to a much more exhaustive series of experiments, and the result was that new kinds of glass were really discovered. The earlier experiments they made were not very remunerative: they took a deal of time, and did not lead to any commercial result; but the German Government generously came forward, and voted a large sum of money in order that the experiments might be continued. The practical result, so far, had been shown in two ways. First of all, telescopes of considerable aperture had been made by Bamberg, of Berlin, as high as eight inches of clear aperture; and as regards achromatism there could be no doubt he had reached a point which had never been attained before. That, of course, would be shown in practical results by the extremely convenient use of deep eyepieces. It was well known that when these were used with a telescope in which the chromatism was imperfect, a flare of clouded fringes was produced; but with the new glass the chromatic aberration appeared to be more highly corrected. Turning to a point more interesting to himself, this glass had been used for the improvement of microscopic lenses, and a new series had been manufactured by the well-known optician, Zeiss, of Jena, and there could be no doubt that he had attained more perfect corrections through a larger extent of aperture than in any of his objectives of previous construction; these objectives were therefore aplanatic in the sense in which the term was used by our classical writers on optics. As regards achromatism, the superiority over lenses manufactured with the older media was unmistakable. Seeing these results, he could not help thinking that photographic lenses also might be much improved by the use of this Jena glass. He thought photographers had a right to expect from opticians that the necessary energy should be devoted to the problem of endeavouring to utilise these new kinds of glass, and to attaining results in photographic lenses comparable with those which had been obtained in the microscope. He was informed by Prof. Abbe that Steinheil had had a good many samples of this glass, and that he had seen his way at any rate to improved forms, and before long he believed there would be an issue of new lenses by Steinheil, made of this material, in which a higher degree of achromatism would be attained with larger and flatter field. If English opticians did not follow in the same path, they would not deserve the support they had hitherto had in England and abroad, where their reputation stood very high indeed. In France, Germany, and Italy, photographers, both amateur and professional, spoke of the quality of English lenses with great respect, and referred to them as being of a somewhat higher standard in the matter of workmanship than almost any produced on the Continent, not in the mere technical execution, but in evenness of quality, so that if a foreigner gave an order to an English firm, he would be almost certain to get a lens of a high standard of excellence. Many people here who had obtained lenses from abroad had not been so successful, and he might say that he had burned his fingers more than once. If you sent for a lens to Paris, you might get a good one, but the chances were you did not.

Mr. Debenham said he thought justice should be done to the memory of Petzval, and he was sorry to hear his lenses referred to by Mr. Mayall as things of the past, and to hear it said that they were infinitely behind newer combinations in aplanatism. According to Mr. Mayall's view, they were the only truly aplanatic lenses, because by his definition such a lens was one free from spherical aberration; and the peculiar characteristic of Petzval's lens which stamped it as the work of a great genius was the freedom of spherical aberration.

Mr. Werge said he should be glad if Mr. Taylor could tell him how to determine the focus of a pin-hole, as pictures of large and small size could be produced thereby.

Mr. Traill Taylor, in reply, said Mr. Werge was very well aware that, according to the distance of the pin-hole from the screen on which the image was received, so would be the magnitude of the image. If it were six feet away it would be large, if only six inches it would be small. The object of the pin-hole was to produce an image of the same dimensions as that given by the lens in question, and that could be done by moving the pin-hole backwards and forwards until the two images coincided. That was all that was wanted. He made no mention of the focus of a pin-hole. Continuing his reply, he said the best lens for a short studio was a short focus lens, and you should get the camera as far away from the object as possible. With regard to lenses for optical lanterns, according to Mr. Mayall there were none, because it was a thing of the past; but he really thought he could not have been mixing so freely in the photographic world as he ought, or he would know that the Petzval was *the* lens *par excellence*—the only thing which could be employed for an optical lantern, either for projecting or enlarging, owing to its adaptability. Petzval's portrait lens was the one for the lantern; it was used in the lantern that evening and everywhere else, and he was a little surprised to hear Mr. Mayall say that it was a thing of the past. The most eminent opticians in the world were making them constantly. They might call them universal lens, or the A, B, C, or D lens, or any name they liked, but they were all Petzval lenses, and they were in constant use. The same gentleman had referred to a cemented back. Among the first lenses that emanated from the factory of Voigtlander were lenses with cemented backs; they were triple compound lenses of enormous aperture and very short focus, capable of working, as was facetiously said, in a coal-cellar. Voigtlander took out a patent for that again a few years ago, and portrait lenses with cemented backs were things of the present day. Mr. Mayall had also referred to lenses being made wholly of flint. When he described Steinheil's invention, he characterised it as being made of two kinds of flint glass, the denser element outside; and all the lenses of the present day characterised by the term "rapid," with the exception of the one he had spoken of as being American in inception, were made with two kinds of flint glass, the denser element outside.

* Abstract of a paper read before the Society of Arts.

A BORE-HOLE in search of coal, said to be the deepest in existence, which the Prussian Government had commenced in the Canton of Merseburg (Saxony), after having reached a depth of 1,738 mètres—therefore more than a mile—has had to be abandoned, as it had come upon porphyry rock.

SCIENTIFIC NEWS.

FROM Dun Echt Circular, No. 134, we learn that elements and ephemeris of Comet B, 1887 (Brooks') have been calculated by Prof. L. Boss, from observations made on Jan. 24, 26, and 29: T = 1887, March 7·95 G.M.T.; π − ☊ 150° 33′; ☊ 276° 38′; i 106° 3′; log. q. 0·23545. The ephemeris for Greenwich midnight reads Feb. 14, R.A. 1h. 47m. 56s.; N. Dec. 73° 27′; brightness slowly increasing. Elements and ephemeris of Comet C, 1887 (Barnard) have been computed by Mr. H. V. Egbert, Albany, N.Y., from observations made on Jan. 23, 24, and 25: T = 1886 Dec. 2·09 G.M.T., π − ☊ 35° 7′; ☊ 258° 52′; i 85° 46′; log. q. 0·17970. The ephemeris for Greenwich midnight reads, Feb. 14, R.A. 20h. 11m. 4s.; N. Dec., 38° 48′; brightness decreasing.

The large southern comet discovered by Mr. Thome at Cordoba on Jan. 18 will probably become visible in Europe, but as its perihelion passage most likely was on Jan. 11, and its brightness has been diminishing since, it is doubtful whether it will be visible to the naked eye, or will long remain within the power of telescopes. According to Dr. Kreutz, of Kiel, the orbit is similar to the orbits of comets 1843 A, 1880 A, and 1882 B, thus supporting an hypothesis that these comets form a sort of system, of which the lately-discovered body is another member.

According to Circular No. 14 of the Liverpool Astronomical Society, the red star Espin No. 142 = 47° No. 194, R.A. 0h. 39m. 55s., N. Dec. 47° 37·6′ [1885], was observed 1886 Nov. 30th to be 8·5. Last night (Feb. 6th) it was only 9·9. It is therefore *var.* The neighbouring star 47°, No. 187, 30s. *s.p.* 1·2′ S. may also be *var.*, as it is now 8·2, while on Nov. 30th it was estimated as 9·2. The red star lies 1m. 34s. *f.* 0° 1·6′ S. of Omicron Cassiopeiæ.

Mr. C. E. Peek, M.A., has issued a brief circular report of the work done at his Rousdon Observatory, Lyme Regis, from which we learn that during 1886 there were 146 nights available, the best month being December, and the worst February. The great nebula in Andromeda (31 M) has been kept under regular observation, and systematic work has been done on a select list of long period variables with the 6·4in. equatoreal. Comets D and E, 1885, A, B, C, E, F, 1886, have also been observed since his last report.

The *Journal* of the Liverpool Astronomical Society for February contains no fewer than thirteen notes on astronominal subjects of interest to observers, including a list of unpublished red stars detected by the late Rev. T. W. Webb.

The death is announced of General Hazen, chief signal officer of the United States.

Col. Sir John Bateman-Champain, R.E., died last week at San Remo, at the comparatively early age of 51. He was at one time director in chief of the Indo-European Telegraph System, having previously assisted in the construction of the land line from Bushire to Teheran, and from the latter place to Bagdad. The deceased officer was, in fact, one of the pioneers of telegraphy, and in 1879 was elected President of the Society of Telegraph Engineers and Electricians.

The Council of the Royal Meteorological Society have arranged to hold at 25, Great George-street, S.W., on March 15th to 18th next, an exhibition of marine meteorological instruments and apparatus. The committee wish to obtain a large collection of such instruments, and will also be glad to show any new meteorological instruments or apparatus invented or first constructed since last March, as well as photographs and drawings possessing meteorological interest.

The Council of the Geological Society have awarded the medals to be given at the anniversary meeting of the society next Friday as follows: The Wollaston gold medal to Mr. J. W. Hulke, the Murchison medal to the Rev. P. B. Brodie, the Lyell medal to Mr. S. Allport, and the Bigsby gold medal to Prof. C. Lapworth. The balances of the funds at the disposal of the society are awarded as follows: The Wollaston Fund to Mr. B. N. Peach the Murchison Fund to Mr. R. Kidston, and the Lyell Fund to the Rev. Osmond Fisher.

In a paper contributed to the Royal Society of Dublin, Professor W. F. Barrett gives an account of his investigations into the physical properties of manganese steel. The makers, Messrs. Hadfield, sent him two wires of No. 19 standard gauge (1 millimètre; ·040in.), one left hard, the other softened by cooling (a special property of this alloy). The wire was found to have an electrical resistance of about 1 ohm per mètre, and the specific resistance in C.G.S. units was 77,000 for a cubic mètre. The susceptibility of the alloy to induced magnetism was only 300, while that of iron is 100,000; and the tenacity of the hard wire was found to reach a maximum of 100 tons per square inch, that of the softened wire being 48 tons. These figures show that the manganese steel should be useful as wire in resistance coils, and as plates in the construction of ships, dynamos, &c.

The judgment of the Court of Appeal in the case of the incandescent lamps with "filaments" leaves the monopoly in the hands of the company who own the Edison and Swan patents; but a final definition of "filament" has yet to be given. One of the judges dissented from the views of the other two, and Prof. Silvanus P. Thompson asks the following question in a letter addressed to the *Times*:—"We may thank Lord Justice Cotton for his timely protest; but what are we to say of the state of things which permits two Lord Justices of Appeal to hand over gratuitously to an inventor that which he does not claim to have invented, and which is not his, and which, if it has not been appropriated by other inventors, certainly belongs to the public?"

The new incandescent method of burning gas, to which we referred in an article on p. 446, has been exhibited at the Marlborough Gallery, 53, Pall Mall, S.W., where 56 burners having the Auer (or Dr. Auer von Welsbach's) cap are arranged in two rows along the centre of the room. A slightly modified form of the Auer cap, or mantle, is being made, we believe, by Mr. A. Paget, of Loughborough, and will shortly be on the market. Laboratory experiments show that the life of the caps can be safely estimated at one thousand hours; but as they are extremely fragile after once being raised to incandescence, care must be taken to preserve them from draughts and from careless handling. In the experiments at the Marlborough Gallery an efficiency of seven and a half candles per cubic foot of gas has been obtained—a very high rate, which if it can be shown in ordinary practice will speedily lead to the general adoption of Dr. Auer von Welsbach's "mantles," or of some similar device. An efficiency of 10 candles per cubic foot was claimed for the Clamond "magnesia basket" (p. 444, Vol. XXXVI.), but in that case it was necessary to provide a blast of air, and the machinery required to produce that would effectually prevent the general adoption of the Clamond system for domestic purposes.

The great dynamo machine known as the "Colossus" has now been running for some months at the Cowles Works, Lockport, N.Y., for at least 20 hours per day, and no accident or stoppage has occurred—a remarkable performance for a machine of the size.

In New York one of the tramway companies has reluctantly abandoned all idea of electricity and resolved to adopt the cable system. In Boston another company which proposed to use the cable has determined to adopt electricity, as it has such "undeniable superiority."

At Maryport recently a remarkable and highly interesting entertainment was given by Mr. F. F. Bennett, the National Telephone Company's manager in West Cumberland. The subject of the lecture was the "Telephone and its Applications," and subsequently a "telephone concert" was given. Wires had been brought into the hall of the Scientific Institution from the central station in Maryport, and a number of telephones were distributed amongst the audience, through which they heard the voice of a young lady singing at Cleator Moor (17 miles away), accompanied on the piano by another young lady at Workington (6 miles distant). Then a cornet solo at Paton (12 miles off) was given, and several pianoforte solos from various places. Similar experiments were made last week between Brussels and Paris, when the Queen of the Belgians listened to the opera in Paris.

M. Hospitalier has been making experiments with electric lights at his private house, using primary batteries (bichromates) to charge secondaries continuously. The bichromate battery is fitted with siphons to secure an automatic change of the liquid; but the cost comes out at 2d. per hour for a 10-candle-power lamp, and that at wholesale prices—viz., 3·75d. per lb. for bichromate of soda, ·65d. per lb. for sulphuric acid, and 3·4d. per lb. for zinc.

At the meeting of the Institution of Mechanical Engineers last week, it was stated that there was a net gain of 34 members, while the capital now amounts to over £18,000. The experiments on riveted joints have been delayed, owing to the non-completion of the testing machine. Fresh apparatus is being constructed for further experiments on friction, and another committee has been appointed to thoroughly investigate the question of the steam jacket, under the presidency of Mr. Davey, of Leeds. Prof. Kennedy is president of another committee, which will draw up a standard system for conducting the trials of marine engines.

The *Lancet* says that "it is very strange that the repeatedly-urged proposal to warm railway carriages by a complete system of pipes heated with the waste steam and the hot air from the engine has not been carried into effect. There would be no serious difficulty and comparatively little expense in putting this plan in operation." Probably the locomotive superintendents would express a different opinion—at all events as to the advisability of adopting that method of warming carriages in express trains.

Preparations are being made at Milan for the International Exhibition of machinery for grinding corn and making bread. This exhibition is of great importance, both from a social and humanitarian point of view. Opportunities will be afforded of examining every mode of bread-making.

Arrangements are being made to hold an international industrial exhibition at Brussels in 1888. The site chosen is that of the 1880 Exhibition, and will include 40 acres of gardens, to be illuminated at night by the electric light, and to contain cafés and concert-halls, besides reproductions of famous ancient buildings.

The Horse-power of a Whale's Tail.—Sir William Turner, the eminent Professor of Anatomy in the University of Edinburgh, recently delivered a lecture to the members of the Philosophical Institution of that city on "Whales: their Structure and Habits," in the course of which he referred to a point of considerable interest to engineers, which was the horse-power exerted by the tail of a large whale. Regarding the length of full-grown whales, Prof. Turner remarked that the porpoise was 4ft. or 5ft. long, whereas the Greenland right whale was from 50ft. to 60ft. long, and he said that the great finner-whale, which frequently visited the British seas, reached the length of 80ft., or even more. An animal of the latter sort was stranded at Longniddry some years ago. After speaking at some length on the structure of whales, the lecturer made some remarks on the rate of speed at which they travelled. It had been estimated, he said, that the Greenland whale could attain a speed of nine or ten miles an hour, and that the finner-whales attained even a greater speed. In all probability the Longniddry whale could propel itself through the water at the rate of twelve miles an hour, and the sperm whale was said to be capable of driving itself along at the same rate of speed. He had asked Mr. John Henderson, of Glasgow, the well-known builder of the Anchor liners, to assist him in arriving at the horse-power which must be exercised by one of these great whales so as to acquire a speed of twelve miles an hour, and he put the case of the Longniddry whale before him. It was 80ft. long, weighed about 74 tons, and had a tail 18ft. to 20ft. across from the extreme ends of its flanges. With these data Mr. Henderson calculated that a whale of the dimensions mentioned, in order to attain a speed of twelve miles an hour, would require to exercise a propelling force of 145 horse-power.—*Engineering.*

[26807.]—SHOULD this meet the eye of Mr. Shearer (reply 60092, p. 415), it has just struck me that the following formula (in which account is taken of the curvature of the earth and refraction) may prove useful to him, as affording a very tolerable approximation to accuracy. If we call the height of any distant mountain in feet D, and suppose we are in a boat close to the surface of the sea, and can just see the top of the mountain above the horizon, we may use $\frac{2}{3}$ D² as the correction for curvature, and take $\frac{1}{7}$th of this for refraction. Hence, we get D², and extracting the square root, obtain the distance of the mountain in miles. For example, the Peak of Teneriffe is 16,000ft. high; how far is it off, when, from the sea-level, we can just see the top of it on the horizon? Here

$$\tfrac{2}{3} D^2 = 16,000 \therefore D^2 = 24,000.$$

Taking $\frac{1}{7}$th of this, and adding it for refraction, we get for distance² 28,000, and extracting the square root of this, 167½ miles.

Discussing, in letter 26685 (p. 429), the observations of the planet Saturn, which have been carried on for some years by Professor G. Davidson, of the U.S. Court Survey, I threw out the suggestion that the anomalous mark on Ring A, known among astronomers as "Encke's division," might be variable. I have since been reading a short notice of some observations made during the last two or three months at the Lick Observatory on Mount Hamilton, in California, with the 12in. equatoreal, which is doing duty there until its mighty successor shall be set up and in working order. Captain Floyd and Mr. Keelar, the observers, say, with reference to the ring system of the planet: "The stripe on the outer ring of Saturn, known as Encke's division, appears as a barely perceptible, ill-defined shade, and is certainly not at present so conspicuous as it is represented in drawings made a few years ago. The inner edge of the inner ring, on the contrary, appears to be more sharply defined than formerly; and the contrast between it and the gauze ring is greater." We know, of course, for dynamical reasons, that the rings of Saturn cannot be solid, and if we admit them to consist of discrete masses or particles, disturbances *inter se*, might quite possibly produce such a segregation of those particles as should lead to gaps, permanent or temporary, in their seemingly continuous surface.

The mention of the Lick observatory suggests to me to say something of what seems to me a very singular proceeding in connection with that Institution: I mean the removal thither on January 8th of all that is mortal of its most munificent founder, and the entombment of his remains on the succeeding day in the pier of the great equatoreal. From a newspaper kindly forwarded to me by a friend, it would seem that the custody of the body was formally transferred to the trustees on the Saturday evening, that the coffin remained in a room in the observatory that night, and that on Sunday, after an address from Mr. Floyd, the president, it was lowered into a cavity in the foundation pier of the great telescope, and permanently built in. I cannot but feel that were I observing alone under the mighty dome, which will so soon roof in the spot where James Lick lies, there would be something eerie in the thought that he, to whose more than princely liberality everything round owed its existence, lay still and cold within a few feet of me. It may be that this absolutely unique interment was carried out by the special wish and direction of the subject of it; but on this point I have no information.

I am sure that "Pynx," and everyone else, must be indebted to Mr. Espin for the admirably clear and apprehensible description of the method of taking stellar photographs which he gives in letter 26757, on p. 475. It contains a quantity of detail, which cannot fail to be useful to everyone interested in this latest method of investigating the structure of the visible universe.

And I am glad, too, to find that another "sprat" which I threw out in letter 26685 (p. 429) has caught such a "whale" as the valuable contribution of "Orderic Vital" to the discussion of the construction of the new form of dialyte contained in letter 26759 (p. 476). With reference, however, to the paragraph with which "O. V." concludes, I should like to say that I cannot admit that anything which can be legitimately regarded as a "discrepancy" does exist "between the theoretical star-discs calculated by Airy's undulatory theory, and those measured in practice"; for the simple reason that the apparent disc has no very accurately measurable boundary. "Orderic Vital" will remember that Sir George Airy showed that if e be the radius of the aperture of a telescope in inches, the extreme diameter of a star-disc in seconds to the first black ring will be $\frac{2 \cdot 76}{e}$. Now, nearly twenty years ago that well-known double-star observer, Mr. George Knott, F.R.A.S., made a series of measures to test experimentally the amount of agreement between theory and observation in this matter, with the results which appear below in a tabular form.

Aperture of Telescope.	Diameter of Disc Calculated.	Diameter of Disc Observed.
Inches.	"	"
7·33	0·752	0·693
6·00	0·920	0·870
4·95	1·113	1.120
4·00	1·380	1·437
3·00	1·840	1·862
2·00	2·760	2·572

Now, in considering this table we must bear in mind what the actual visual aspect of a star is as viewed with adequate magnifying power in a first-class telescope. Imprimis, we have a disc brilliant in the middle, but rapidly degrading into an absolutely black ring; then comes a brilliant ring, then another absolutely black one, and so on; the maxima degrading with such rapidity that at the first, second, and third we have the $\frac{1}{57}$th, $\frac{1}{240}$th, and $\frac{1}{620}$th of the illumination at the true centre of the disc. The very way in which this disc itself degrades towards its edge renders that edge itself almost impossible to define with rigid accuracy. I wish that "Orderic Vital" would test this for himself with any form of micrometer he may prefer. If he will, I think he will agree with me that the agreement between the calculated and observed diameters of the discs in Mr. Knott's measures is quite close enough to confirm, rather than to throw doubt upon, the undulatory theory of light as developed by Airy.

Has "Norfolk" (letter 26767, p. 477) ever had anything practically to do with road-making in his life? I ask this question because, while he is careful to calculate the weight to be raised annually at (what he calls) "the public expense," he wholly omits to make the slightest estimate of the cost of levelling his "five hills and four vales, each hill averaging fifteen yards in altitude," which, instead of falling upon those only who contribute to the traffic, really would have to be effected at the public expense. Let him inquire of some competent civil engineer, and publish the result in these columns. Having done this for his hypothetical five miles of road, let him go on to compute how many millions it would require to materially alter the gradients in the two counties of Devon and Cornwall alone; and finally, perhaps, he would not mind mentioning, confidentially, where the money is to come from. Burdens on land at present are just about as much as it can bear; and it is the proverbial last straw that breaks the camel's back. Road surveyors, quarry owners, quarrymen, navvies, carters, and roadmen wholly refuse to accept remuneration in the shape of "*foot-pounds.*" They have a prejudice, well or ill-founded, in favour of the twenty-shilling article; and in this form, malgré "Norfolk's" elaborate calculations, they would insist on having it.

I am very sorry that I have innocently wounded the susceptibilities of "Another Fellow of the Royal Astronomical Society" (letter 26782, p. 480) by my comments on the absurd nonsense talked about Mr. Roberts's discovery of 20 planetoids in Orion! Even your correspondent, though, is now driven to speak of Sir R. Ball's encouragement of Mr. Roberts's delusion as unfortunate laudation. I was not criticising Mr. Roberts's photograph, save in this connection, and am quite content to admit that it shows more detail than others previously taken of the same region. But Mr. Common and the MM. Henry *frères* (to say nothing of others) had shown Mr. Roberts the way; and, after all, it is only a question of protracted exposure. I know, of course, in common with every working astronomer, that refraction distorts the sun's image, converting it into a quasi-ellipse, with, by the bye, its major axis horizontal. I have further seen a cognate effect produced upon Jupiter when near the horizon; but that stars whose discs subtend an angle of 0·276" should be converted into perceptible ellipses (with *their* major axes lying in the wrong direction!) is "rather a large order." But one lives and learns. One word as to my "pungent personalities." I must be curiously constituted indeed to indulge in them in connection with anyone whom, as in the case of Mr. Roberts, I should not even know by sight if I met him; while as for the effect predicated of them by my confrère in his concluding sentence, I can only conceive it to be produced in those who have some friend or friends engaged in picking the public pocket in what has been recently termed (in a gush of advertising penny-a-lining) "our national institution at South Kensington, the too modest home of British science"!

Since the above was written (and quite possibly in type) I have seen the letter (26788) of "A Third F.R.A.S." on p. 499. What I described—and must persist in regarding—as the "imperfect astronomical experience" of the gentleman who could for an instant believe that he had photographed 20 new planetoids in and about 42 M Orionis (!) is spoken of in very much less euphemistic language by this fresh interlocutor; who whoever he may be, can obviously speak with an amount of personal knowledge and authority to which I have no claim. When Mr. Roberts sees what letter 26782 has elicited, he may, I think, well be tempted to exclaim, "Save me from my friends!"

If "Inquirer" (query 61505, p. 486) is limited to three eyepieces for his 3½in. telescope, he should obtain them of powers of, or about, 40, 120, and 250. The longer the focus of any telescope the better, so long as it does not become unwieldy.

I do not possess the work quoted by Mr. Godden in query 61542 (p. 487), and hence have no means of reference to the context; but as a mere statement of fact, the quotation he gives is simply absurd. The earth was in perihelion, and hence moving at her greatest speed in her orbit at 8 p.m. on January 2nd. At noon on that day at Greenwich the clock was 4m. 14·88s. before the sundial; and it was not until 4m. 14·88s. after the clock marked noon that the shadow of the gnomon fell on the meridian line. So much for the condition of things in perigee. When, though, we come to July 2, at 9 a.m. on which day the sun was in apogee, and when, according to the "Astronomy" the clock should be before the dial, we find that its author has stumbled into a correct assertion, for at noon on that day the sun does not south until 3m. 41·88s. after clock noon, or the clock shows noon 3m. 41·88s. before the dial does. Possibly the book goes on to explain how part of the equation of time is due to the inclination of the sun's apparent path (the Ecliptic) to the Equator; but taking the isolated sentence as quoted by your correspondent, the first half has obviously been incorrectly copied by the compiler of the volume whence it was derived.

I may tell "W. T. N." (query 61561, p. 487) that, if not absolutely instantaneous, the velocity of the influence of gravitation must be sensibly or practically so. A very little consideration will show him why. Light takes some eight minutes and a quarter to come from the sun to the earth. Suppose for a moment that gravity acted at the same rate: then, of course, the earth would feel the pull of the sun eight minutes and a quarter after she had quitted the place where the sun began to exert it; so that it would not be in the line connecting the earth and sun when the influence reached the former, but in the line joining them eight and a quarter minutes before. By the familiar diagram of the resolution of forces, this diagonal pull may be resolved into two, one attracting the earth to the sun, and the other hastening her in her path. But hastening her in her path means enlarging her orbit, lengthening the year, and so forth: nothing of which, as we well know, has happened. Hence gravitation must traverse space millions of times more swiftly than light. It has been calculated that the earth's pull on the moon must operate in less than 1-50,000,000th part of a second!

I have just received a copy of the *Annuaire* of the Brussels Observatory for 1887, and, I am

bound to say, a mass of the most valuable information it contains. Many pages are devoted to tables of physical units and constants, a detailed account of absolute physical measures, &c. There is also much of interest and use to the geodesist, while the ephemerides and details of the Solar System are excellent. Of course, a good deal of the work is taken up with matters geographical, topographical, and meteorological of purely local interest; but the larger proportion is adapted to the wants of every astronomer and man of science. The Abbé Spée continues to defend Secchi's theories against all comers, and repeats some of the "common forms" of the Solar Physics ring in this country. As, however, this will take in but few people indeed nowadays, his paper may be read with advantage. The work concludes with M. Lancaster's list of observatories, astronomers, and instrument makers, carefully revised and brought down to the present day. This is a real addition to the volume. In fine, the chief fault to be found with the present issue is that M. Folie repeats his ridiculous innovation of last year, and fills his monthly ephemerides with the name of a saint for every day in the year. I must venture humbly to reiterate my opinion, that in a purely scientific annual the columns given up to SS. Ludger, Agapet, Waudru, Clet, Pacôme, Zéphirin, Mummolin, and the rest of them, are very indefensibly wasted.

I see that the observatory of the Liverpool Astronomical Society has begun to issue its own publications, in addition to that capital general *Journal* of the Society, with which we are all familiar. The first number of this fresh issue lies before me as I write. It consists of two divisions: the first devoted to photographic stellar photometry, and the second to spectroscopic observations of stars. The photographic part gives the magnitudes (photographic as well as ocular) of 1376 of the D.M. stars, and must of necessity prove most valuable for comparison in future years with photographs of the same objects. It is instructive to note that here is work being done—and well done—by private enterprise, for which it was attempted, not so long since, to obtain a genteel form of outdoor relief from the national Exchequer for a person at Brompton.

"Hermes" (query 61577, p. 508) will find a description of Dent's meridian instrument (which was called a dipleidoscope) in several of your back volumes. For example, he may consult Vol. XXIV. pp. 429, 462, 510, and 555, to begin with.

A Fellow of the Royal Astronomical Society.

ALPHA FORNACIS (Herschel 3555).

[26808.]—THE pair α Fornacis (or 12 Eridani, as it is sometimes termed) is included in the double-star catalogues of Messrs. Flammarion and Gledhill as a probable binary, owing to supposed changes in its angle and distance. As the two stars are animated by a large common proper motion amounting, according to Argelander, to 0·707″ in the direction of 27·2° annually, there can be little question as to the actual physical connection of the components, but the micrometrical measures are somewhat discrepant. The principal ones are as follows:—

H_2—

306·1° : 3″ ± : 1835·87 (1 night) 20ft. reflector.
310·7° : 5·30 : 1836·40 (2 nights) 5in. refractor.

Jacob—

309·9° : 4·09 : 1847·05 (10 obsns.) 3¾in. refractor.
308·3° : 3·39 : 1851·09 ? 6·2in. refractor.
309·8° : 3·29 : 1852·99 ? 6·2in. refractor.
310·0° : 3·31 : 1856·16 (21 obsns.) 6·2in. refractor.

C.O.—

316·0° : 2·44 : 1877·81 (3 nights) 11·2in. refractor.

Hall—

311·7° : 2·60 : 1879·53 (4 nights) 26in. refractor.

β—

318·2° :ntgvn: 1879·68 (1 night) 6in. refractor.

Hall—

311·5° : 2·60 : 1880·25 (3 nights) 26in. refractor.

It seems probable that the apparent diminution in the distance is due to personal and instrumental causes. Sir J. Herschel remarks that, owing to the faulty micrometer, very little weight indeed can be attached to his measures of distance with the 5in. Tulley at the Cape; in fact, they are little better than estimations. The large star is No. 84 of Gore's "Catalogue of Suspected Variables." There are some curious discordances in the magnitudes of the small star also: Herschel, Jacob, and Stone call it 7 magnitude, Hall 8 magnitude, while Burnham, at Mt. Hamilton, rated it as low as 10·5 magnitude in Struve's scale. Gore failed to see it with a 3in. achromatic in the Punjaub in 1875.

H. Sadler.

Might I ask "A Third F.R.A.S." (letter 26788, p. 499) what learned society in England was made a laughing-stock to the world by Mr. Roberts's wild theory of the discovery (?) of the planetoids in the nebula of Orion? Not the R.A.S. certainly, as Mr. Roberts's paper on the subject was, of course, not read, nor was his photograph handed round at the meeting. Presumably, if someone chose to present us with a photograph of, say, the Rumtifoozle, we should be obliged to accept it, though it would not be hung up in the library or meeting-room. I am bound to say that I have seen far worse astronomical photographs than those of Mr. Roberts's—of portions of Cygnus, for instance. As his photographs of the nebulæ in the Pleiades agree *inter se*, though they were taken at different dates, and as they show the nebulæ discovered by MM. Henry, as well as a considerable amount of nebulosity not shown by them, as their telescope is inferior in light-grasping power to Mr. Roberts's, I do not think that there can be much doubt as to the actual existence of the nebulæ in question. Of course, the star discs are far inferior to those on MM. Henry's photographs, as, no doubt, those members of the L.A.S. who inspected my collection at the last meeting of that society will have noticed.

H. S.

STAR PHOTOGRAPHS—COMES TO POLARIS AND ALDEBARAN.

[26809.]—MR. ROBERTS is quite entitled to use his own discretion as to whether or not he should reply to the criticisms of "F. R. A. S."; but it is difficult to see why those criticisms should be made a peg upon which to hang the offensively personal remarks of "A Third F.R.A.S.," on page 499. This letter reminds me of a "coloured" preacher whom I once heard, who prefaced his sermon by announcing that "he would take a text, that he might be free." I think "A Third F.R.A.S." would have done well to imitate the candour of the Ethiopian in question. Pray, what interest is it to know who it was that instructed Mr. Roberts in the method of developing his dry plates? Men are not born in these days with a complete knowledge of such a technical subject as photography, and must perforce have assistance or instruction from some external source. I fail also to see wherein Mr. Roberts has shown any discourtesy in not announcing to whom he is indebted for the essential instruction in the photographic process to which "A Third F.R.A.S." makes allusion. Surely a successful artist is not thought to be discourteous because he omits to announce the name of the teacher under whom he studied every time he exhibits a work, neither do I see what useful object is served by parading the shortness of the time during which Mr. Roberts's name is said to have been before the astronomical world. It would be well if every astronomer could show such results as Mr. Roberts has been able to do in so short a period.

I may add that I have no personal acquaintance with Mr. Roberts, and that my knowledge of astronomical photography is of the smallest; but having seen some of the photographs of stars and nebulæ at a recent meeting of the R.A.S. when Mr. Roberts exhibited them in connection with his paper then read, I think his work quite deserving of the warm commendations then passed upon them by Mr. A. A. Common and others then present. I think he is to be congratulated on being able to produce star photographs comparing, as they do, very favourably with those of MM. Henry, and with apparatus which he then readily admitted to be capable of much improvement. If I were to conclude my letter by following the example of "A Third F.R.A.S.," I should, I suppose, have to subscribe myself "A Fourth F.R.A.S.," but for the obvious reason that I have nothing to say requiring the concealment of one's personality under a *nom de plume*, I shall abstain from doing so.

With reference to Mr. Gemmill's remarks (letter 26789, page 499), respecting the discrepancies in the comparative magnitudes of the *comes* of Polaris and of Aldebaran I can fully endorse all he says.

The *comes* of Rigel also seems considerably underrated when compared with the *comes* of Polaris and of Aldebaran; perhaps its alleged duplicity may have some slight influence upon its magnitude.

I called attention to the obvious differences in the real magnitudes of the *comes* to these three stars, as compared with those given in "Cel. Objects," in a letter to the "E. M." some time ago. (Vol. XXVIII. p. 541.) **W. Goodacre.**

Forest Gate, Feb. 5.

THE NEW BROOKS COMET.

[26810.]—WHILE sweeping the northern heavens on Saturday evening, January 22, with the 9in. silver-on-glass reflector, I discovered a new comet in the constellation Draco, approximate R.A., 18h. 0m. + 71°. I was soon enabled to detect motion, which was in a north-east direction. Telegraphic announcement was made by 9 o'clock, and it was cabled to Europe the same night. I secured another observation of it on my return from the telegraph office. Sunday night was cloudy; but last evening, January 24th, it was beautifully clear, and the observation was very satisfactory. The comet was then about one degree nearly north of Chi Draconis, and in the same low-power field. The same night the comet was observed at the Rochester, Albany, Cambridge, and Washington Observatories. Dr. Swift, at the Warner Observatory, Rochester, made its position at 7.30, January 24th, R.A., 18h. 20m. 28s., + 73° 36′ 34″. Comet is of moderate size, round, with slight central condensation, and visible in moderate apertures. **William. R. Brooks.**

Red House Observatory, Phelps, N.Y., U.S.A., Jan. 25.

COMES TO POLARIS.

[26811.]—IN reference to the question of variability of the *comes* to Polaris (letter 26789, p. 499), I append the following notes made in observing Polaris with a 2⅝in. refractor, power 68.

1875, March 27.—Studied Polaris very hard tonight, and found it tolerably difficult to see the companion. Webb calls it a "common test," but I did not find it so, although I generally agree with what Webb says.

May 22.—*Comes* seen very well.

July 18.—Just detected in bright twilight.

1876, May 7.—Saw the *comes* nicely in a bright sunset sky.

1877, June 3.—*Comes* of Polaris seen most distinctly—in fact, no difficulty with it at all; A whitish, B bluish.

Although the above are somewhat spasmodic, the remark against 27th March, 1875, shows that it was not so easy to be seen on this occasion as on others. **E. E. M.**

BLAIR'S NATURAL PHILOSOPHY—DIPSOMANIA.

[26812.]—I HAVE been looking through "Blair's Grammar of Natural and Experimental Philosophy," and on page 117 it states that "the sun's diameter being on the 31st December 31′ 45″, and on the 2nd July 32′ 45″, or nearly one-thirtieth longer, and consequently so much nearer, and increasing and decreasing gradually, it is evident the orbit of the earth is an ellipsis. Newton found the mean diameter of the sun to be 32′ 12″, but, as above, it is 32′ 15″. In January, therefore, the earth is in perihelion, and in July in its aphelion, and having a smaller circle to traverse in its perihelion half than in its aphelion half, it is eight days longer in performing the aphelion half of its orbit than the perihelion half."

Should not the apparent diameter of the sun seem larger when the earth is in perihelion? and how can the earth be in aphelion in July, if, as it states there, we are so much nearer?

On page 144 of the same book, in treating of the moon, it says: "To Dr. Herschel we are also indebted for an account of several burning volcanoes, which he saw at different times in the moon. In Vol. LXXVII. of the *Phil. Trans.*, he says: 'I perceive three volcanoes in different places of the dark part of the new moon. Two of them are nearly extinct, or, otherwise, in a state of going to break out. The third showed an actual eruption of fire, or of luminous matter.' On the next night Dr. Herschel saw the volcanoes burn with greater violence than on the preceding evening."

Has any observer of the moon seen anything of the same kind lately? Perhaps Mr. Elger could enlighten me?

I have been anxiously looking forward for the results of Mr. Edge's case. Can he, or "Garrison Gunner" give us further particulars? If "Garrison Gunner" will extend to me the same offer he made to Mr. Edge, I will advertise my address, as I would give much to reclaim a near and dear friend, who is fast becoming a confirmed drunkard.

T. C. H.

ELECTRIC LIGHTING BY LECLANCHES.

[26813.]—IT is quite possible, as Mr. Conry states, to light incandescent lamps by means of Leclanché cells. I have employed this method for the past seven months, and can recommend the Leclanché as the cheapest battery for the purpose where a temporary light only is required.

My battery consists of 27 No. 1 cells, arranged in three rows of nine, and I use 5c.p. (nominal) lamps. Only one lamp is used at a time; one is in my bedroom, another in w.c. When this installation was new, the battery kept a lamp glowing brightly without any perceptible diminution of light for ten minutes or more. I did not test its capability in this direction, as I did not want to waste power. One day a switch was accidentally turned on and the battery ran down. Since that time the light given by the lamp falls off rapidly in use; however, the light given is ample for the purpose required. I can turn on a lamp at any time during the night without getting out of bed, and can see the time by the clock from which the lamp is distant about 6ft. Another lamp in the cellar enables me to draw a glass of beer without the trouble of carrying a lamp, and the nuisance of having it blown out by the draught up the cellar stairs. Another lamp on the staircase affords suffi-

cient illumination when going to bed after turning out the gas downstairs. Twenty-seven cells is the minimum quantity that will work my lamps effectively; thirty-six would be better. Of course much depends upon the lamp. I tried various combinations of cells to get the best results.

A. Percy Smith, Rugby.

ELECTRIC LOCKING FOR RAILWAY SIGNALS.

[26814.]—IF you will be good enough to insert the inclosed description of my system, I think it will answer the letters which appeared in your last number, and explain the system, which does not appear to be properly understood by your correspondents.

First I will take a double line of railway, and three stations — A, B, C. For simplicity "up" trains only, as the same system of working applies to "down" trains. Conditions at each station:—Levers of starting signals locked, indicator over lever showing "lock on." Instrument at B and C showing last train arrived:—A green disc, with "train arrived" on it. If this system is worked by, and in connection with, the block telegraph instrument, then the discs or needles of the block instrument show the indications instead of special or separate discs.

A has a train to leave his station: his starting signal lever being locked, he cannot lower it. A then sends a bell code (as arranged) to B, who, seeing by his instrument that the previous train has arrived (and by its arrival the instrument has been rendered capable of being again worked), sends a current by key or plunger, and takes the lock off of starting signal at A. The signalman at A can then lower the signal, and the train leaves. On A putting the lever back, it is mechanically, not electrically, locked again by a catch lock. When B sent the current to A, his instrument indicated the same by a white disc "line clear," howing him that he had given "line clear" to A and taken his lock off. When A received the current, and his lock was taken off, the lock itself sent a current working the indicator to "lock off," and as soon as the lever is put back, the indicator shows "lock on." On the train's departure A gave the bell signal "train on line" on the red key of his instrument, which brings up a red disc "train on line going" on his instrument, and rings the bell at B, and drops a red disc at B's instrument showing "train on line coming." Now A cannot move his lever again till B unlocks it, and B cannot unlock it (his key or plunger being locked up) till the train that has been allowed to come on by B has passed over the treadle, which action causes a green disc in his instrument to drop showing "train arrived," and resets the instrument, which is, until then, locked up by the action of taking the lock off of A's signal for the train to come on, and the same process is carried on from B to C and forward throughout the line. Now if, say, B does not put his lever back after the train has gone on to C, the signal would be down, and no danger can arise from this, as when A asked B to unlock his signal for another train, B's signal lever not having been put back by B to danger renders it impossible for B to take the lock off the lever at A for the following train to come on, because the wire by which he sends the current to A is severed, and it is only joined again when B's lever is put back and locked, so that he must put it back before he can take A's lock off again, and in putting it back, it is again mechanically locked, and must be unlocked again from C before he can lower the signal again; the same arrangement is made at every station. If A, being a terminal station, does not put his lever back, the ordinary interlocking system would necessitate his having to do so in order to set the road for the next train or engine to shunt into the station, when it would be locked by the act of putting it back. If the terminal station has one or more platforms from which a train can start, the signals for the platforms are interlocked mechanically, and one must be put back before the other is lowered, and with my electrical locking attached to these, after one signal is lowered no other can be until the train is out of the first section and the lever has been put back and locked; and this can also be otherwise arranged, if this is not considered sufficient.

For single lines the system is the same, with the addition that when a lock has been taken off for a train to proceed, not only cannot another follow, but one cannot leave in the opposite direction. Should it be necessary from any cause to cancel a signal, the lever which has been unlocked must be moved and replaced before the signalman can take off the lock for a train to come in the opposite direction. If the instrument fails, it fails on the side of safety by locking all up; but provision is made until it is put right, so that it can be worked in such cases under special directions, so as not to upset the regularity of the traffic. I am aware some are of opinion that the train should put the signal to danger as it leaves the station automatically. Some years ago I thought this a good plan, and with my electric signal I arranged an entirely automatic system, that the train itself should, on leaving B, ring a bell to C, put up a signal to danger at B to protect itself till it got to C, at the same time take down the signal it put up when leaving A. But I have somewhat altered my views, and prefer two strings to my bow: one that there should be retained all the intelligence that can be obtained from human agency—the signalman, and that if he should go wrong, it should be mechanically impossible for him to do so. From the correspondence that has passed, it seems to be thought that the signal is locked by the electric current from the other end. This is not so. It is only unlocked by current, and is mechanically locked by a catch lock on being put back. The aim is safety. Quibbles may be raised as to the lever not being put back in order to lock it; but if a second train cannot come from the stations in the rear until it is put back and locked, I maintain most emphatically that the system is absolutely safe, and meets all requirements.

In my system one line wire only is required between stations for sending all the necessary signals for the bell, lock, and indications, and at a junction one instrument is sufficient for working any number of lines approaching it; but only one train can be allowed to come on, and a second one cannot follow until the first has cleared the junction and passed the clearing point authorised by the traffic managers. It is also well adapted for intermediate sidings between stations, and much time is saved by its use.

C. E. Spagnoletti.

The Poplars, Aberdeen-place, London, N.W., Feb. 1st.

DEPOSITION OF ALUMINIUM.

[26815.]—A MISTAKE is made in reference to Mr. J. Baynes Thompson's process for the deposition of aluminium. The reduction was not at 500° Fahr., but from 120° to 150°. The solution was of aluminate of soda, and the intensity of the current about 6 volts. The reaction is not electrolytic, but secondary and chemical by nascent hydrogen.

Mr. Thompson has for long deposited aluminium from aluminate of soda. Some years ago I read in the *Chemical News* that aluminium could not be thus deposited. In reply, I left with the editor a strip of copper with half of its surface coated with aluminium. No notice was taken, however, of this practical correction.

Wm. White.

The Laurels, Cheshunt, Herts, Feb. 1.

IRON v. STEEL.

[26816.]—OF late years steel has been rapidly taking the place of iron for all structures of strength, especially so in rails, bridges, and ships. The chief advantages of steel are lightness, strength, and durability. For instance, in the case of steel rails, it has been found by experiment that a steel rail will last out sixteen or eighteen iron ones, because the iron one does not wear uniformly, but gets into a series of hills and hollows, which soon render it useless, while the steel one wears gradually and uniformly its whole length.

It has further been found that it requires 30,000,000 tons to wear $\frac{1}{16}$in. off a steel rail. In fact, we could not do with iron rails at the present day, as the enormous amount of traffic on our railways would render them comparatively useless in so short a time that they would constantly require to be relaid, thus hindering the traffic to a great extent.

The width of the table of double-headed steel rails is $2\frac{1}{4}$in., and is curved to a radius of $5\frac{1}{4}$in.—the depth of the rail. The web is $\frac{5}{8}$in. thick. The shoulders are inclined at an inclination of one in two.

The great durability of steel rails is due to the fact that steel is homogeneous and fibreless, and therefore it lasts, or rather holds together, as long as there is any of it left.

In the construction of bridges and ships and other structures requiring great strength, steel is preferable to iron, especially so in swing bridges and ships, as it combines strength and lightness. By the use of steel, structures may be lightened 23 per cent. By the regulations of the Board of Trade the greatest stress per square inch is not to exceed $6\frac{1}{2}$ tons, and for iron 5 tons per square inch. At the Forth Bridge at Queensferry the amount of steel required for the two main spans alone has been estimated at 42,000 tons. If the bridge were of iron, the weight would be increased by nearly 10,000 tons (adding 23 per cent. on).

Would it have been more economical to use iron, or would the extra cost of the steel be more than that of 10,000 tons of iron?

Boilers are now being made of steel, which reduces the weight about 10 per cent., and the thickness of the plates by 20 per cent.

The tensile strength of steel is about 29 tons per square inch, and an elastic force of 11 to 16 tons per square inch. Drilling the holes does not seem to weaken the plates; but punching the rivet holes weakens the metal by about 30 per cent. If the plates are annealed, however, the strength is restored again.

The use of steel for ships has proved most satisfactory. On several occasions, where vessels went ashore, or came in collision, the sides of the vessels were merely bent in, but not broken. A saving of 20 per cent. in the weight has been effected by the use of steel plates, combined with a strength 30 per cent. superior to that of iron. Let us take an example:—An iron girder has to bear a strain on the top and bottom flanges of 650 tons, then the area of the top flange (taking 5 tons per square inch as the compressive strength) would equal $\frac{650}{5} = 130$sq.in.; but suppose the girder were of steel, then (taking $6\frac{1}{2}$ tons as the compressive strength for steel) we have $\frac{650}{6{\cdot}5} = 100$sq.in. Thus the area is reduced by 30 per cent. by substituting steel for iron.

In the manufacture of steel there are three processes—viz., Bessemer, Siemens, and Thomas-Gilchrist.

The chief point in the Bessemer process is forcing air through the molten metal in a large converter. The oxygen in the air burns and produces an intense heat, and a chemical change takes place which separates the carbon and other impurities from the molten metal. The time required for the "blow," as it is termed, is about 20 minutes.

The Siemens, or open hearth, process takes about four hours; but by this process the metal can be examined from time to time, so as to ascertain its condition.

Large quantities of steel are now made from ore not formerly suitable for steel, by the Thomas-Gilchrist process, which is merely an extension of Bessemer's. The main difference is in the lining of the converter.

Steel is now largely used for castings, in preference to iron. Lately, however, castings have been made from malleable iron by the "Mitis" process. Malleable iron, when heated to melting point, does not run freely into the mould. It has, therefore, to be heated a little above that point; but when it reaches so high a temperature, it is found to absorb gases which produce flaws and cavities in the castings, thereby rendering them useless. In the "Mitis" process a small amount of aluminium is added to the iron, which causes it to melt at a much lower temperature; it therefore does not absorb the gases, but produces a good sound casting, free from all flaws and defects.

Portobello, N.B. James G. Shepherd.

BURNT AIR.

[26817.]—IT is a pity that some correspondents (see letter 26792) do not take to heart the editorial heading to the correspondence column, and *write what they know*. It is doubtless true that steam may be decomposed when passed through a *red hot* iron tube; but that the aqueous vapour in the air suffers the same change by contact with a hot stove is an absurdity. The most probable explanation of the difficulty is that the organic matter in the air is burnt, with the formation of a small quantity of ammonia. A. P. S.

SUNDIAL TO SHOW MEAN TIME.—TO "E.L.G."

[26818.]—SOME years ago "E.L.G." gave, I think, as a sort of challenge or crux to the scientifically-inclined of our contributors, the construction of a sundial to show mean time all the year round. Might I ask him, as no one has taken it up, will he supply the answer himself if such a dial be a possibility.

Windmills.—I am glad to see Mr. Vallance defending his windmill, as he is well able to do, against all comers. He may remember writing me privately an account of its results and construction, which so convinced me of its practicability for the purpose he recommended it for—viz., ploughing a steep hillside—that I commenced the construction of a mill; but circumstances prevented my ever completing it.

Some short time ago I saw in your periodical an illustration of a horizontal mill, which it seems to me would be very effective, and well designed for a small motive power, very simply and easily constructed. If any one is interested, I might be able to look it up and send illustration.

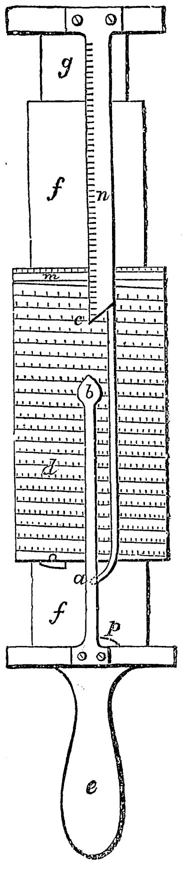
Lathe Construction.—Might I ask "F.A.M.," if he has it still, could he return me a very rough sketch of my method of fitting the guide-screw nut on front-slide lathe? I sent it to him in reply to his challenge to prove that the form and fitting of the bed proposed by me was not what he called a "paper bed." I do not know whether it is my plan he has adopted in his article on the subject which appeared some time ago. I have been working at the subject on my own lines, and my sketch of this

has gone astray, which is my excuse for troubling him or writing anything on lathe matters in the "E.M." **Fred. Carre.**

PROF. FULLER'S SLIDE-RULE.

[26819.]—YOUR correspondent Raymond (26804) has given a very brief description of Prof. Fuller's slide rule. I think it would be of interest to many of your readers to have a fuller description of this excellent rule, which is becoming very popular where there is much calculation being done. I therefore inclose a good illustration by Prof. Fuller with his description.

Its range is greater than most arithmetical machines, as, besides the operations of multiplication and division which many instruments can only perform, results requiring the reciprocals, powers, roots, or logarithms of numbers, can be quickly and easily obtained by its use.



The rule consists of a cylinder *d* that can be moved up and down upon, and turned round, an axis *f*, which is held by a handle *e*. Upon this cylinder is wound in a spiral a single logarithmic scale. Fixed to the handle is an index *b*. Two other indices *c* and *a*, whose distance apart is the axial length of the complete spiral, are fixed to the cylinder *g*. This cylinder slides in *f* like a telescope tube, and thus enables the operator to place these indices in any required position relative to *d*. Two stops *o* and *p* are so fixed that when they are brought in contact, the index *b* points to the commencement of the scale. *n* and *m* are two scales, the one on the piece carrying the movable indices, the other on the cylinder *d*.

The use of slide-rules has been confined to roughly approximate calculations, as the length of scale hitherto made was sufficient only for about 160 divisions. In the new rule the length of scale is 500in. and the number of divisions 7,250, consequently the approximation obtained by its use is sufficient for most of the calculations required by engineers and architects, and for many of those required by actuaries.

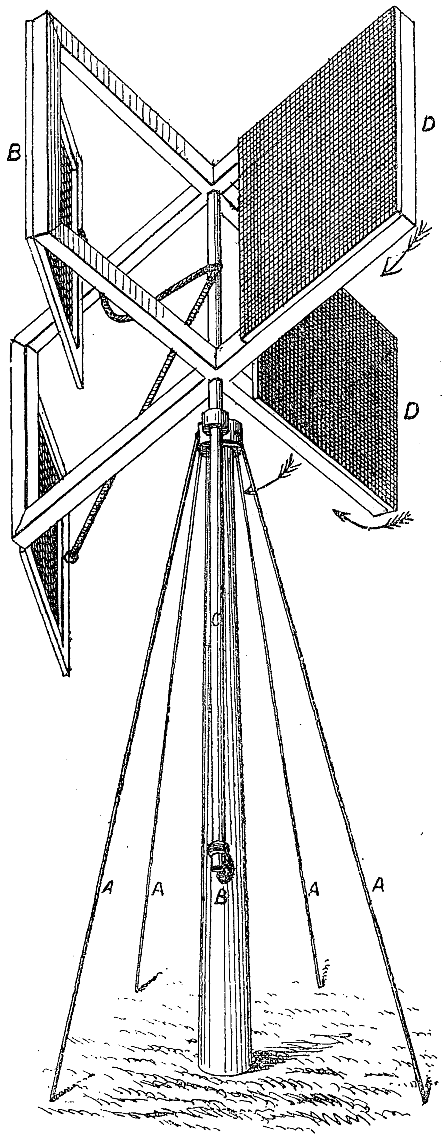
For taking out bills of quantities this rule will be found of especial value, as by its aid the squaring and cubing of quantities is easily and quickly performed. **W. F. Stanley.**

HORIZONTAL WIND POWER.

[26820.]—MY model being constructed on a scale of 1½in. to a foot, or one-eighth of the intended full size, I find, with a fair breeze of wind, it gives me the following results: It lifts a 4lb. weight perpendicularly one foot in one minute; but my trials having been made in a walled garden, near trees, I feel certain the little motor will give much better results when I can find a free current of air without eddies, in which to make a further trial.

My idea of a full-sized machine is two 20ft. crossbeams 11in. deep and 3in. thick, giving 4 arms, each 10ft. long; 4 spars 2½in. diam. at the centre, 20ft. long, 10ft. being above and 10ft. below the crossbeams; with sails 20ft. high lashed to masts, and extending 8 or 9ft. to the sheets. I hope ere long to give better accounts; but I could not well keep silent after promising to give results. I think I have too many powers on, having a screw on upright shaft working in a wheel, with pinion in second wheel with barrel. I shall try more direct results next week. **Wm. Hosken.**

[26821.]—I HAVE read with great pleasure the discussion going on in "Ours" on the above subject, as it is a subject that I take a great interest in. Inclosed is a very rough sketch of a horizontal windmill, which has occupied my "odd thoughts"



for this last two years, which, with your permission, Mr. Editor, I submit to the friendly criticism of your readers.

The sails, D D D D, are made of sailcloth tacked on to a wooden frame, which is hinged to the arms of the mill. The post B is a scaffold-pole of the height required, braced with iron rods fixed into the ground, and fitted with tightening screws similar to those attached to telegraph posts.

The power is communicated by means of a pair of bevel cogs to a heavy flywheel running on a stud fixed at B, one of the cogs fixed to the lower end of the rod C, and the other fixed to the flywheel. I think the sketch will explain the rest; if not, I shall be glad to give any further information in my power.

Walsall. **F. Russell.**

[26822.]—OUR thanks are due to Mr. Boothroyd for the information which he supplies in his last letter (No. 26,760). It will assist those who are interested in this matter in arriving at some conclusion, at least, so far as Southport is concerned. Though the average seems low (18⅔ miles per hour being the highest for one day), I think it can be shown that it is sufficient for the purpose of electric lighting. Of course, this would not be the highest speed attained during the day; it is the average for twenty-four hours. It is highly probable that during some parts of the day the speed attained would be from 30 to 40 miles per hour, and during other parts would fall to 12 or 8 miles per hour. We know that the speed of the wind varies considerably during each day, and if the hourly variations could be ascertained during the seventeen weeks, our way would be much clearer. But as the returns do not show the hourly variations, I think we may venture to make an estimate of the probable variations. For this purpose I divide the day of twenty-four hours into four divisions of six hours each, and assume that the wind varies in its velocity during each of these divisions. The figures which I give, when added together, amount to the same as those given by Mr. Boothroyd for a day of twenty-four hours. I have adopted Mr. B.'s American wheel to base my calculation as to power developed. Taking week ending June 25th, and the day of greatest velocity during that week equals 448 miles, or an average of 18⅔ miles per hour, I will assume that the speed during that day would show the following variations:—

	Velocity per hour.		Pressure.	Power.
6 hours	36 miles	= 216	6lb.	6H.P.
6 „	18 „	= 108	2 „	2 „
6 „	12 „	= 72	¾ „	¾ „
6 „	8⅔ „	= 52	⅜ „	⅜ „
		448		

Taking again week ending Oct. 15th, which stands midway between the weeks of greatest and least velocity, I apply the same test to it:

6 hours	24 miles	= 144	3lb.	3H.P.
6 „	12 „	= 72	¾ „	¾ „
6 „	8 „	= 48	⅛ „	—
6 „	3⅓ „	= 20	—	—
		284		

The same principle applied to week ending Nov. 26th, which is the week showing the least velocity of the seventeen weeks, I get ½H.P. for six hours only.

It will be seen that if my assumptions are correct, or something approaching to correctness, that we may get a power equal to 3H.P. for six hours out of the 24 hours, at least during one day in each week at an average. The other days in the week will vary, of course, between the day of greatest velocity and the day of least velocity during the week. I think that we may fairly assume that during three days at an average in each week, there would be sufficient pressure to develop a power of from 1H.P. to 3H.P. for six to eight hours daily.

Of course, there will occasionally be a week with very little wind, as for instance, week ending Nov. 26th; but it will be seen that the week preceding, and the week following, show a very high average velocity. So that with storage sufficient for a week's consumption, electric lighting by wind power may succeed at Southport. **Gwalia.**

[26823.]—IN your impression of 21st Jan., "A., Liverpool" (26755, p. 456), for whose judgment I have much respect, states that the vertical windmill "is infinitely superior in power to any horizontal," in which I agree with him; though that is not the whole question, and when he adds that "it would not require nearly so strong a framework to resist storms," I am entirely at variance with him, unless he limits his comparison to "such a cumbrous, and top-heavy concern" as that of Mr. Vallance, which he apparently had in his mind when he used the expression.

The old English windmill, of full power, was always understood to require a conical tower to be built for its support: only smaller ones, perhaps 10ft. shorter in the arms, were erected as post-mills—and when we consider that whatever the power of the wind on the sails may be, its first impact is against the tower itself, and in fact so continues throughout, we can understand how great the strain must be when equal to eight or perhaps ten horses pulling with all their strength at its apex, to overturn the structure. Now a well constructed horizontal wind-engine, something on Samuel Miller's plan, (see his patent of 1777), need not be of any considerable weight, and would need no more support than sufficient to resist the absolute power given out by the machine at its best, which might be one or two horse perhaps, within the moderate and manageable compass of 12ft. arms or so, giving a diameter of 24ft. over all. The vertical windmill, on the American plan, can be set up almost anywhere; but it has this disadvantage—that however high you have to go to get the true breeze, clear of surrounding objects, you must go as much higher above your platform as the radius of the wind motor at the very least, which necessarily limits it to small power, better and easier obtained, per-

haps, and certainly much cheaper, by a horizontal machine of a light construction.

The lofty Toronto mill, at the exhibition, had what a mechanic termed "a ghastly look, and no one but a steeple-jack would like to ascend it."

Q. E. D.

MESSRS. SCHOTT AND CO.'S NEW OPTICAL GLASS.

[26824.]—THE new list* of glasses for optical purposes, issued by Messrs. Schott and Co., of Jena, is a very comprehensive one, embracing glasses of a very wide range in refraction and dispersion. I am induced to send the list to these columns because I feel assured that numbers of opticians, amateur and professional, both at home and abroad, will desire to obtain and to experiment with this glass. For telescopic, microscopic, photographic, and spectroscopic purposes, in each and all, I believe it will prove of essential service. For microscopes its success seems to be proved; while for telescopes, although we do not yet hear of a double objective made of the new glass, without doubt such will be done before long. In the latter case, it is not so easy to experiment as in the former; for, in addition to the greater expense, and the larger amount of material to be manipulated, there is another matter which needs careful attention. However rational may be the spectra furnished by two different kinds of glass, it is equally necessary that there shall be considerable difference in their absolute dispersive powers. The minimum difference practically allowable is a point which, so far as I am aware, has not yet been settled. For the dense flint glass, a focal proportion of about 3 to 5 is a common one; or for the lighter kinds, about 3 to 4. The question is how much lower than 4 can the second number be?

The new list contains forty-four glasses; twenty of these belong to the crown, and twenty-four to the flint variety. Of course, very many are of the ordinary kind, and demand no special notice; but nineteen are of essentially new composition. Ten of these are crown, and the remainder flint glasses. The refraction varies from 1·5047 to 1·604, and the dispersion from $\frac{1}{70}$ to $\frac{1}{55{\cdot}3}$ in the crown; and from 1·5503 to 1·9626, and from $\frac{1}{55{\cdot}2}$ to $\frac{1}{19{\cdot}7}$ in the flint. There is thus a very wide range of refraction and dispersion in both varieties. A low refraction does not necessarily always accompany a low dispersion; neither does a higher dispersion necessitate a proportionately higher refraction. Some of the glasses seem very remarkable in this respect. For instance, there are two crown glasses of practically equal dispersive power, while the index of refraction in the first is 1·5100 and in the second 1·5906. And in a pair of crown and flint, with indices of 1·57, their dispersive powers are nearly as 4 to 5. Several other peculiarities will also call for notice as we proceed; but for the present these few preliminary remarks will be sufficient. I shall divide the list into two parts, one of which accompanies the present paper; the other will follow, with the necessary explanatory remarks, next week. The names of those glasses of essentially new composition are printed in italics.

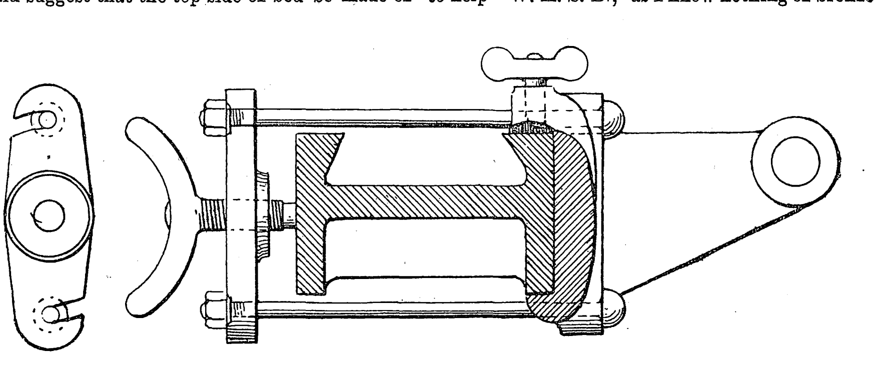
Orderic Vital.

(*To be continued.*)

* This list as sent to me is in German. I am not aware whether an English edition has been published; but in the present case, through the kindness of a friend who takes great interest in optical and astronomical matters, I have been able to get the explanation of the tables "done into Inglysshe."

"F.A.M.'s" LATHE DESIGN.

[26825.]—I THINK an alteration in the section of bed shown in No. 1124 would be advisable. I would suggest that the top side of bed be made of



the same general form as the lower. This would result in several advantages: the top V of apron could be raised, the vertical front being also raised on each side of seat of traverse slide till near top of bed. With the high centres, this gain would be valuable. The heads would have a broader base —they seem rather narrow now—and would be more easily fitted, the bed also requiring less planing and getting up. The heads could be aligned from the back of the lathe, where the surface would be larger, and rather easier, if anything, to align to front than the V in front. To allow the saddle to pass the fast head, the flange on far side could be drilled, and two $\frac{5}{16}$in. screws put in to pull it up to edge; the bolt shown in first drawing would hold it well down. A convenient fastening could be made for loose head as shown in sketch. The apron could not be racked past it; but as it could be instantly lifted off bed, that is not a great disadvantage. The loose head could be very firmly held and readily pulled to alignment. It could also be made to set over for turning taper to some extent if that was required. The fastening would clear till the loose head was close to traverse slide, and would be firmer than simply tightening into V's.

The increased clearance for the clasp-nut would also be a gain, and the top of bed would be a better surface for odd purposes. I am still unreconciled to the top rest, and would prefer to use a stepped block for drill-spindle.

Vulcan.

LATHE MATTERS.

[26826.]—I SEE that I am not likely to be able to help "W. A. S. B.," as I know nothing of bronze or spun work. Will he not send the accurate drawing of the candlestick, even without the details?

Referring to Mr. Alf. Hartley's letter, would it not be well if he would give a short account of the contents of his father's book? I understand it contains *working* drawings of the geometrical chuck, of the mandrel lathe, and of the medallion apparatus; if so, it would be a thousand pities it

should be lost to the world. Until Holtzapffel's Vol. VI. appears we have no full description of rose-engine work that I am aware of.

"Vulcan's" chuck attachment is very ingenious; but, alas, how much more complex than the well-known screw! My chief difficulty in making it would be to get the points of the screws to enter fairly and bear correctly in the coned holes of mandrel. I don't feel that I could trust those two points with all the holding and driving, as they would only touch at a point each, not bear all along like the wedge; but then the wedge stops the hole in a bored mandrel. **F. A. M.**

RADIAL DRILLING OF DIVISION PLATE.

[26827.]—THIS plan has been several times advocated in the ENGLISH MECHANIC; it does not, however, appear to have been noticed that the plan is of no real advantage for use with an *adjustable* index. For if, with one particular length of index the various zero holes are on the circle whose radius is the index, then the shortening or lengthening of the index will nullify this; consequently, unless the index is always used at exactly the same length as it was when the holes were originally drilled, we shall not be able to shift from one zero hole to another without rotating the mandrel. **C. W. Bourne.**

ROAD REFORM.

[26828.]—I MUST apologise to "G. F. F." for not having replied sooner, but have been very busy. He says in letter 26751 that the traffic on turnpike roads has increased tenfold since Macadam's time. I certainly doubt whether the increment is so considerable—at all events, on country highways, which one often finds, except near towns or other sources of local traffic, almost deserted. As an instance, I may mention the Great North Road. I should be glad to know whether any figures are available giving the average weekly traffic, both now and in Macadam's time, on country roads in different districts, for they, of course, would settle the point.

The other question, as to the efficiency of small and large stones for bearing heavy loads, such as traction engines, seems to me to depend for solution on the breadth of tire of the weight-carrying wheels. If this be adequate—and I believe a certain legal standard exists—the passage of a traction engine will injure the road no more than will that of any other vehicle.

Though identical with "B. B.," I am compelled to sign differently, owing to the author of query 61478 having assumed those initials.

Bertram Blount.

[26829.]—I AM afraid no general measure of alteration of gradients and consequent deviation from the present sites of the roads throughout the country is likely to be undertaken at present; but I think very great improvement may be made in a short time, and at a comparatively small first outlay.

In the first place, I think all roads should be thoroughly underdrained, so as to insure a dry bed of at least 4ft. deep. This may be accomplished in most cases by a 4in. or 5in. pipe drain up the centre, or in some cases one up each side of the road. All other improvements should be preceded by this measure. Then the surface water should be got away from the road in the shortest possible way, and not allowed to run down the sides, as is very usual, for long distances, and in many cases land drains have been allowed to be emptied on the side of the road, thus ruining the foundations of the road.

Having got a dry bed, the next business should be to form the road to a proper transverse section, viz:—of a gradient of 1 in 30 from the centre to each side, and this should be rigidly enforced so as to allow the traffic to use the entire width instead of only 4ft. or so of the centre. Having got the road into proper form, the next step should be proper metalling, and this should be done from side to side, making the sides as strong as the crown. Now there are two opinions as to whether a rigid or a flexible road should be aimed at. If the former the road should be carefully pitched and then metalled; but if a flexible one, the metal should all be broken to the same size. From my experience of country roads, I certainly prefer the flexible, as I have seen a road on drained clay with metal broken to go through a 2in. ring, stand the heavy traffic of traction engines without breaking up. All metal used should be granite or greenstone broken to a 2in. gauge and screened free from sand, &c.

We now come to the maintenance, and in this I think the greatest improvement could be made as follows. The greatest obstacle to rapid and economical communication in the interior of the country is the obstruction caused by loose, broken stones put on the roads for their repair in the autumn especially: this at once increases the draught to such a degree as often to bring carts laden to a complete standstill, to say nothing of the danger and annoyonce of riding and driving over such surfaces. The road sides during the year are dotted with heaps of broken and unbroken stone. I think all this could be cheaply overcome if each Highway Board provided itself with a steam-roller, and when new stone was laid, that the road should be rolled smooth and firm, thus providing a good and safe travelling surface and at the same time a surface from which the wet would escape with the least chance of sinking into the foundation and making it like a wet sponge.

If the Society for the Prevention of Cruelty to Animals would take up this question, it would save many a poor horse from sore shoulders and broken knees, and many a poor traveller from a broken neck. **R. P.**

THE COLD IN CANADA.

[26830.]—I NOTICE in the MECHANIC for March 26th, 1886, "Inventions and Discoveries" (25514), page 84. I have seen here at Swift Current, and more frequently in Manitoba, some 300 miles east of this point, icicles from 6in. to 1ft. long hanging from the nose of an ox when on the trail. That is not at all unusual when the thermometer registers from 35° to 55° below zero (Fahrenheit). Of course, any person who might be exposed for any length of time to such extreme cold, if not properly clad, would be frozen to death.

I have, however, travelled hundreds of miles when the temperature has been between 30° and 50° below zero without any ill effects whatever—in fact, on account of the exceeding dryness of the atmosphere, it makes one feel "good," as we say in this country—i.e., exhilarated.

When the temperature has been about 45° below zero, I have thrown a cup of boiling water in the air, and it has descended upon a board in the shape of small ice crystals, without wetting the board in the slightest degree. As to the ink freezing on the pen while writing, that is quite a common occurrence; this ink was quite solid until thawed out this morning, and if I was to attempt to write away from a fire, say, in my bedroom, it would immediately freeze on the pen and stop my scribing.

I bring new milk home to my family wrapped up in a piece of paper in a solid lump frequently, and it will remain perfectly new and fresh until wanted.

I have a wish to try some thermo-electrical experiment, by making use of this extremely low temperature, but do not know how to proceed.

W. G. Knight, Meteorological Observatory.
Swift Current, N.W. Territories, Canada,
Jan. 21.

MR. HIGGS' COIL.

[26831.]—AT the request of Mr. Boothroyd (letter 26636) and those of your readers who have not been fully replied to by post, I beg to hand you the required details of my coil.

The Core: $14 \times 1\frac{1}{4}$, No. 20 B.W.G. soft iron wire, known in Birmingham as winding wire, not subsequently annealed.

The Primary: 3 layers No. 12 double cotton-covered copper, the whole finally immersed in melted paraffin and placed in ebonite tube $\frac{1}{4}$in. thick.

The Secondary: 14lb. No. 36, 2lb. No. 35 double silk-covered, in all about $14\frac{3}{4}$ miles, wound in 52 discs; outer diameter, $5\frac{1}{2}$in. at middle, decreasing to $3\frac{1}{4}$in. at ends; inner diameter, $2\frac{3}{8}$in. at middle, increasing to $2\frac{7}{8}$in. at ends; length of body, 11in.; terminals $10\frac{1}{16}$in. apart; insulation between discs, from 3 to 6 thicknesses paraffined blotting-paper, varying as the differences of potential between the parts of any two adjoining discs.

The Condensers: 3 in number; 40, 30, and 20 sheets of tinfoil $10 \times 7\frac{1}{2}$; the sheets of each half were all soldered between copper strips $\frac{1}{2}$in. broad; connections from primary to condensers are copper bands 1in. broad.

The Contact Breaker: A slight modification of the ordinary vibrating spring pattern.

Results: $9\frac{1}{2}$ to $10\frac{1}{16}$in. spark with one quart bichromate cell, single zinc 6×3in.

Should any further explanation of a specific nature be required, such will be most willingly replied to in its proper place. Moreover, those of your readers who can make it convenient, particularly those who know what a spark really is, are cordially invited to inspect the coil. No kind of weather interferes with the above-named results.

George Higgs.

THE LUMINIFEROUS ETHER (OR ABARON?)

[26832.]—SUPPOSE your room nearly filled by a cage or frame, bearing a million compass pivots, or 100 layers, each containing 100 in length and 100 in breadth. On these place 1,000,000 equally magnetised needles; or better, only 500,000, omitting half the pivots, that each may be equidistant from its 12 nearest neighbours. When all are at rest, the repulsion of similar poles keeps them all parallel. Now let an insect set one near the centre swinging. Every swing will be imitated, and travel outward in a spherical wave-surface that enlarges till embracing the whole roomful; and whatever the number of swings, that number of waves will spread all with one and the same velocity, like sound-waves in air, or circles from a stone in water. Now that is a parallel whereby we may figure to ourselves a propagation having all the known properties of light, plane-polarised, circularly or elliptically polarised, &c., without any "jelly," the inventor of which, known or unknown, I look on as a supreme—well, calves' foot possessor.

Of course, as Mr. Grey tells "Sigma," our knowledge by no means stops at there being "something" to convey light. Nor does it stop at the rate of travelling, some 120,000 times what gaseous elasticity can insure for sound; nor yet at the knowledge how many vibrations per second each ether particle has to make; as, for red light a billion to each single vibration of the note F^1, or for blue a billion during one vibration of B^2. The main distinction from sound is known to be that, whereas particles of air, in propagating sound, are displaced, or perform excursions, and approach or recede from each other, light is all propagated by luminifers that keep their places, neither approach nor recede; but each only swings on its own centre. No condensations and rarefactions, like those in sound-waves, are here supposable.

Not only is the ether or sky-stuff as likely to be atomic as other things; but it is the sole thing that we are compelled to regard as formed of atoms. All weight stuff of the chemist we are at liberty to suppose, if we will, infinitely divisible, provided only the skystuff, caloric, "abaron," electric fluid, or whatever we may call it, permeating all the weight stuffs, be in atoms. Moreover, we are not obliged to think the atoms nearer in a compressed gas, or less numerous in rare air than in dense, or even in planetary space than in glass or gold. The difference may not be in number of atoms, but only that those in the planetary space are free, while those in the gold are each loaded with a definite load of weight-stuff. Again, we are not bound to suppose that any weighty body moving displaces any sky-stuff. The heaviest and swiftest planets may be passing through it as a net through water. Even a meteoric pebble that dashes into our upper air with such velocity as to displace a million times its own bulk or weight, and drag after it a vacuum as big as a balloon, with its air-skin heated to vivid whiteness, may not displace any sky-stuff. Though we can hardly doubt electricity and magnetic action to involve displacements of sky-stuff, mechanical motions may not involve any. We can hardly doubt that the force whereby each luminifer atom, when set wagging, causes the next to wag, is the very same whereby the primary current in a "dynamo" excites the secondary, or a magnet magnetises its approaching or receding keeper. Hence, for above a generation, at least ever since Faraday's optical experiments in the magnet's field, the "electro-magnetic theory of light" has been most tenable and attractive, whether Maxwell worked at it or not; though not only "A. X.," but the oracular editor of *Knowledge*, has lately so ignored as to sneer at the very mention of any so called.

As for "Abergwili," and what he fancies he was taught at school (p. 451), he must have deserved the dunce's cap there. Long before our time, all schoolbooks had told that five miles was the height, not that our atmosphere *has*, but that it *would have* if all compressed to the same density as at sea-level. Also that about 50 was the least it can actually have (to account for the twilight), but it *might* be several times this. Observations of meteors now indicate about twice. The idea of its universal extension is utterly untenable, because we can receive and measure star rays that have passed nearer to Jupiter or Saturn than the distances at which their attraction would make such air far denser than what we breathe. Indeed, there would be enough near Jupiter to bring his inner satellite to rest in very little time.

The absurd dragging in of "old Hebrew writings"—no, of versions from them—as if capable by themselves of teaching points of science, as I complained at p. 264 and 284 (Nos. 1130, 1131), always brings out such an error as Mr. Grey's, p. 451, that the Hebrew writings have not the "slightest bearing on any questions of science." They will always have immense bearing on some, and we never can tell on what questions.

Nothing in this century's discoveries will be so memorable as the unexpected ways they have constantly been illustrating old Hebrew writings. Hardly till yesterday did science suspect, though now pretty certain, that this earth was ages older than the sun. Hardly till this generation was it certain that there are many worlds having time marked by days, evenings, and mornings, though without a sun as yet. But Hebrew writings had always told of our earth as having had days before a sun existed to rule them; and had continually

been laughed at therefor. Again, look at the present geology's attempts at explaining the most recent changes, how the Glacial age passed into the present (man being in both, as Boucher de Perthes was led, only by his Bible, to discover in gravel; and yet the hugest and most abundant animals of the Glacial age having vanished from every continent when most swarming, and in all lands disconnected from Asia, the merest fragments of the former found, and not of "the fittest," but some of the *unfittest*, species alone surviving). Much of Lyellism and Darwinism will doubtless be kept to a sort of penal immortality of ridicule, being more laughable than aught in Scripture became at any time. And all the while, Hebrew writings had given the perfect clue to the whole enigma. About 50 centuries ago there was a day that a fresh sea fell from the sky. It fell the same day on all the continents and islands of both hemispheres; the quantity, as dredgings have apparently shown, such as to raise the ocean level about 600ft. That bears precisely on all questions respecting the Glacial age ending and this one beginning, and exactly meets every fact of them. E. L. G.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[61084.] — **Fireclay.**—See my letter inserted in December or January. I now see that No. 1 is called a clay (see Vale of Neath clay). Bloxam says, "It is locally known as clay"; but it is not really a clay. I was not, I admit, quite right in all that I said; but I have not been set down as I requested if I was wrong. A better heat-resisting furnace is wanted for Fletcher's furnace burners. What?—R. S. T.

[61131.]—**Electric Cautery.**—From what has already been published regarding this particular cautery in my possession, "Ohm" cannot but be aware that the data required for the employment of the formula supplied by Mr. Conry never having been known to me, it is impossible to comply with his request to demonstrate the same. My remark that "I was perfectly able to use the formula" could not, and did not, apply to my own cautery, although "Ohm" makes it do so. Nothing more than mere ability to make use of the formulæ was claimed—the data as usual being supposed to be known—a point which I was under the impression (a mistake I now see) "Ohm" had denied. I would prefer an instrument to record the current; but if a formula is considered to be the better way I am able to use it. In this connection I may be allowed to say that I have accepted Mr. Bottone's kind offer of one of his 5s. ammeters to test and report. Let me add, in case "Ohm" thinks I am shirking the point, that I sent a concise answer to query 60892. The question addressed to me—not directly, but as an aside—in a third party's reply, I left unanswered, because, in my judgment, it had no bearing on the original query.—A. DUNLOP STEWART, M.B.

[61131.] — **Electric Cautery.** — TO MR. DUNLOP STEWART.—I have made the test of Mr. Bottone's ammeters to which he invited me, and am pleased to say that it was quite successful. I had to go down to Sutton on business, and on the way back called in at Mr. B.'s place. He showed me the ammeters, the scale of which is graduated to tenths of an ampère; I connected to the terminals a rough single-couple "thermopile," made of two bits of wire, respectively No. 16 copper and No. 20 German silver, about 4in. long, and soldered together, and applied to the soldered joint the flame of a small-spirit lamp. Having had a little experience in the making of thermopiles of various sorts, I knew that the utmost current that any heat short of melting the solder would get out of such a couple as the above would certainly not exceed one-tenth ampère. After about two seconds' heating the needle moved, and in about five moved across the scaled space of one-tenth of an ampère, going back with the same regularity as the wire cooled when the flame was removed. I tested several and found the results similar. This, considering that the price is only 5s., is very good indeed, and I can certainly advise you to use these instruments if one-tenth of an ampère is a sufficiently near measurement for your wishes. Your easiest way would be to make up some battery that will heat the cautery to rather over the degree you require, having one of these ammeters in circuit (they are practically of no resistance—about ·00 something of an ohm), and gradually lower the battery plates into the solution till you get the cautery right, and then note the current drawn by the ammeter.—EDWARD CONRY.

[61145.]—**Does It Boil?**—I have to correct a clerical error in my last—*more* rapidly, in the ninth line, should be *less* rapidly. Certainly my desire to help "Weald" has been rewarded by a better grasp of the subject, consequent on the study of various standard books. "Weald's" last contribution affords ample proof that I was right. The atmosphere can exert no direct pressure on vapour, and its action is wholly different from that of a pump plunger or a column of mercury. No; vapour filling a flask at 20° C. at a pressure less than standard will not collapse into water when the flask is opened to natural air. The air does not diminish the space available for vapour. If, on the other hand, the space in the flask were diminished, say by pouring in mercury, the temperature remaining constant, condensation would ensue. The vapour tension proper to 20° C. is nearly 0·7in. of mercury. Now, if water be introduced into a receiver exhausted to, say, 1in. of mercury, the pressure will instantly rise to 1·7in. If the receiver contain dry air at a pressure of 30in. the introduction of water will cause the pressure to rise more slowly to 30·7in. of mercury. Does "Weald" attribute this rise of pressure to solvent action? Again, 100° C. is the temperature, not of boiling water, but of steam at standard pressure, for boiling water is always hotter than its vapour. Water gives off vapour from its surface until the space above it is full of vapour at a pressure which increases with the temperature. The pressure of the atmosphere is powerless to prevent it; the only thing that can prevent evaporation is the presence of the full amount of its own vapour. Now, suppose a vessel of water heated from below attains the temperature of 100° C.; the vapour rising from the surface is of standard pressure; but since the pressure within the liquid is greater than standard pressure by the amount of the surface tension of the liquid, and the head of water above any given portion, no vapour can be evolved except at the free surface, and any bubbles that are formed where the heat is stringent will collapse as they rise through the water; this is simmering or parboiling; a little more heat, and the temperature throughout the mass is sufficient for vaporisation.—W. A. S. B.

[61190.] — **Differential Feed.**—I am glad another correspondent has taken up this; but he says I have answered one question incompletely. I reply—Which? As regards his strictures, I would point out that wheels 128 and 80 give a pitch of ·15, and wheels 130 and 80, which I suggested as perhaps near enough, give ·155, not ·15626 as "R. T. S." says. I have endeavoured, in replying to this, to use only the ordinary change wheels, which all practical men prefer to use, in preference to cutting a wheel, if it can possibly be avoided, and to avoid compound gearing.—T. C., Bristol.

[61255.] — **Embrocation.** — At the time of writing this query, I was under medical treatment; but it was to no practical purpose. I managed to get over the attack, but no thanks to the doctor for it. I have studied diet, and also consulted four medical men during the last five years. These latter did no good, and only caused me to become an unbeliever in doctors altogether. — A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61283.] — **Hot-Air Engine.** — This querist might be referred appropriately enough to your back numbers; for instance, No. 1099, p. 148. The displacer is almost necessarily of larger area than the working cylinder.—E. G. M.

[61291.]—**Ageing Wood Carvings.**—I have to thank Messrs. Bretton and Bottone for their kind replies in your issue of the 7th Jan. Whether it is that cypress wood is not affected by the fumes of ammonia, or that my ammonia is not sufficiently pungent, I cannot say; but the results are not at all satisfactory. It is impossible for me to employ stains, as such an application would injure those parts affixed by glue, such as the shavings and chips that form border traceries.—NAWS.

[61294.]—**Octave Coupler.**—"T. D." will find a diagram that will assist him in No. 953, or perhaps a more specially useful illustration in No. 528. The only practically useful method is the duplication of the backfalls—putting the coupler backfalls on the skew. I have not heard that anyone has invented a device which takes less space.—ORGANON.

[61300.] — **Saccharine.** — Most hydrocarbons like saccharine are known to be both antifermentive and antiseptic; but what is it "R. S. T." wishes to know. The authorities have been given in the various articles on the subject published in your columns, and your correspondent can scarcely mean to assert that because saccharine passes through the organism "unchanged" it can have no effect. Mercury is a typical instance of a substance which passes through the organism unchanged, and there are many others.—F. I. C.

[61303.]—**Boiler Water.**—This query is headed "Chemical"; but I have taken the liberty to alter it, as the querist wishes to know what is the matter with the water he draws from his kitchen boiler. It is rain-water, taken from a galvanised iron tank, and conveyed by iron and lead piping. Being water practically free from lime, while charged with more or less chlorine, it no doubt dissolves the zinc from the coating of the tank, and is, perhaps, further contaminated by the piping. Perhaps a remedy might be found by making the water artificially hard, and so getting an incrustation on the tank, &c.—NUN. DOR.

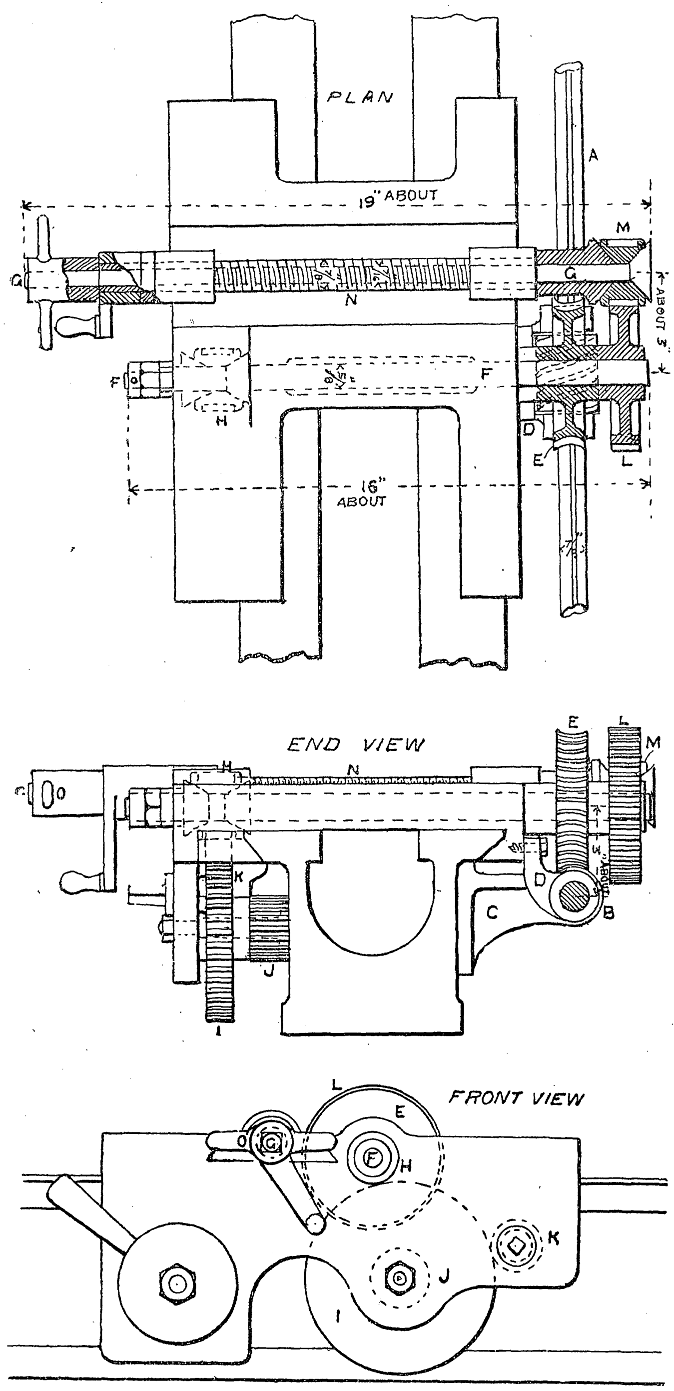
[61307.]—**Occultation of Aldebaran.**—I am obliged to your correspondents for the information given me. My object is to obtain true time, and the calculation of occultations for this purpose are evidently too laborious. I now propose to use a plumb-line and small aperture, about 4ft. away from it, as a rough transit instrument. Will some of your readers who may have tried this plan, say the size of aperture and of wire best suited for the purpose; also distance horizontally between aperture and wire?—A. WEST.

[61409.]—**Coating Steel Springs.**—The reply of "Canadian" on p. 483 is one of a class which is becoming too frequent; but happily most people know what to expect when "information" cannot be made public, and the querist is asked to advertise his address. It so happens that I have had a good deal of American coppered wire through my hands, and I have no hesitation in asserting that the copper does not last long if handled—and that is what the querist does not want. There is plenty of coppered wire used in this country, and there is no secret in its preparation; but unless electroplated, it will not stand handling. Some firms adopt one process, some another; but all are to be found in your back volumes, in Watt, or in Gore. "Canadian's" "fear" is misplaced.—NUN. DOR.

[61420.] — **Loco. Fire-Grates.** — The figures given by your correspondent "Amateur" in answer to this question do not seem to agree with modern practice. He states that—1, there should be "about 80sq.ft." of heating surface "to each sq. ft. of grate bars"; 2, "upon each sq. ft. of grate about 1cwt. of fuel should be burned per hour"; 3, from 8lb. to 11lb. of coal are consumed in evaporating 1c.ft. of water—i.e., 1lb. of coal evaporates from 5·71b. to 7·81b. of water. 1. Now, in the Dreadnought the ratio of heating surface to grate area is 68·4 to 1; in the Gladstone, 72·25 to 1; in the new C. R. single bogie, 62·36 to 1; in the new C. R. coupled bogie, 62·1 to 1. 2. If the Gladstone were to burn 1cwt. of coal per hour on each sq. ft. of grate with the 5 p.m. train *ex* London Bridge, its fuel consumption would be 49·61b. per mile! 3. The Gladstone evaporates about 12·95lb. of water per pound of coal consumed, and the Dreadnought 9·491b.—A. W. BURCHELL.

[61438.] — **Measuring Cloth.** — Yes, truly; when the first term of the series is $12 + d$, then the common difference will be $\frac{60}{199}$, and in this case the sum of the series, or the length of the cloth $= \frac{199}{120} c^2 + \frac{c}{2} - 244\frac{4}{5}$; from which formula a table may be computed, which would include the numbers given by "Workman" at p. 504.—MILVERTON.

[61442.]—**Weight of Moist Air.**—I can sympathise very much with "W. S. A." in his efforts to explain the seeming paradox that is involved in his question, and for the purpose of making the matter as clear as possible I have examined the weights he has given me. The weight of a cubic foot of vapour at the given pressure I found to be sufficiently correct; but the other two weights seem to have been interchanged—that is, the weight of the dry air given to the moist, and conversely, for it will be observed that the weight of a cubic foot of dry air is greater than that of a cubic foot of moist air. I was, therefore, induced to recompute the weight of a cubic foot of dry air by an independent method, and at the given temperature and pressure I found it to be 488·71 grains. Now, to ascertain the actual amount of the discrepancy between the two formulæ, in order that I might show what it is owing to, I took the weight thus found for dry air as the given quantity, and computed from Watts's formula the weight of a cubic foot of moist air, and found it to be 478·02gr. Then, taking this as a given quantity of moist air, I computed from the second formula the weight it gave for a cubic foot of dry air, and this I found to be 489·94gr. Now, had the two formulæ been equivalent, I ought to have got 488·71gr., the weight I began with for dry air; but there is a discrepancy of 1·23gr. to be accounted for. Now, referring back to page 484, and to the manner in which the third formula was deduced, it will be seen that V″ was made equal to V. In this case, since the volume of dry air is taken at one cubic foot, the volume of moist air would be $\frac{p}{p - E}$c.ft., or 1·0639c.ft., and since the volume of vapour was made the same, there would be an excess of ·0639c.ft. vapour beyond a cubic foot. Now, multiplying this by 19·84, the weight of a cubic foot of vapour, we find that the second formula gives an excess of vapour equal to 1·267gr.,



and this will account for the discrepancy between the two formulæ. It is scarcely fair to deal with the formulæ (2) and (3) at p. 484 as if we were dealing with weights, from the first of which Watts's formula has been derived by making s equal to unity and the unit of weight equal to the weight of a cubic foot of dry air, the second formula referring the specific gravities to dry air as the standard fluid, and the third to moist air as the standard fluid.—MILVERTON.

[61323.]—**Back Shaft for Sliding and Surfacing.**—The arrangement for self-acting, sliding, and surfacing by means of a back shaft is shown in the accompanying figures. A is the back shaft, $\frac{7}{8}$in. in diameter, which is driven by reversing motion like that described on p. 416 of the present volume, the direction of revolution of the shaft for up and down sliding being changed by the reversing gear. The shaft is carried in suitable brackets C, bolted close to the ends of the bed. The shaft is grooved throughout its length, and carries a worm, B, of about $\frac{1}{2}$in. or $\frac{5}{8}$in. pitch, and say $2\frac{1}{2}$in. long, keyed upon it, not fast, but making a sliding fit, the bearing D of the worm being screwed to the back of the saddle. As the shaft revolves the worm is bound to revolve with it, because of the key, but is not constrained endways excepting by its own bearing D, between whose bosses it is embraced. As the worm revolves it drives the worm wheel E, and this again gives motion to shaft F for "sliding," and shaft C for "surfacing." Taking shaft F first, the wheel E is keyed upon it, and therefore always turns the shaft. The pinion H at the other end is not keyed, but is a loose fi but can be tightened instantly by the nut and cones. Being tightened, H drives I and J, the latter being the rack pinion. K is simply a pinion gearing with I to effect the racking by hand. For surfacing, the wheel L, keyed on the same shaft as the worm wheel, drives the pinion M, which is tightened between cones similarly to H. The screw N of the cross slide is therefore hollow to allow the spindle C, which tightens the cone, to pass through to the front of the lathe, where it is embraced by the nut O. Either spindle can, therefore, by tightening or slackening its nut and cone, be immediately put into or out of gear. Not having a plan view of your saddle, I cannot put in many dimensions; but these you could soon fill in as most suitable. I rather doubt if you could apply so much gear to an ordinary saddle made for sliding only, since, having an extra spindle F, you want increased width, and, properly, more thickness if this spindle goes, as it should, through the body of the metal, a chambered hole being first cast through. The position of your leading screw is not figured; but, from its appearance, I think it would be fouled by wheel I, and in that case the face of the saddle would have to be brought out farther from the lathe bed, or a saddle of a different form substituted. There are other methods in use to effect the automatic motion of the two shafts—as friction discs applied to the faces of the pinions, and sometimes small clutches. This is more suitable, however, for a 6in. lathe.—J. H.

[61452.]—**Electrical Apparatus.**—Many thanks to Mr. Conry for his help. What is his opinion as to charging secondaries by any primary battery? I have little time to clean and recharge a dozen or so large cells every second or third night; but if once a week would do, I would try it. My experience of primary batteries is that they are not to be relied on for electric lighting except on a very small scale, and where they will get almost unlimited attention. Four lamps of 5c.p., taking 2 ampères each for four hours a night, would suit my purpose splendidly. I have never yet seen or heard of an installation depending on primary batteries alone, and a permanent job being practically worked for over a week or two. If any one has details of domestic lighting by primary batteries to show, I am sure it would interest more than—ELECTRICAL STUDENT NO. 2.

[61450.]—**Engine Details.**—ERRATUM.—Connecting-rod, 18in. between centres; not 9in. as printed on p. 484.—A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61485.]—**Steel Spiral Springs.**—It is rather difficult to gather from "Spring's" letter what he wishes to accomplish; but the following formulæ will give him the means of ascertaining the stiffness of any given spiral spring in pounds per inch (by which is meant the weight that will deflect it 1in.), and also the maximum safe load that may be put upon it:—

Let D = Diameter of wire.
R = Radius of coils (centre to centre of wire).
n = Number of coils.
W = Weight in pounds that will deflect the spring 1in.
M = Maximum safe load in pounds

$$\text{Then } W = \frac{180{,}000 \times D^4}{n \times R^3} \quad \ldots\ldots\ldots\ldots (a)$$

$$\text{And } M = \frac{12{,}000 \times D^3}{R} \quad \ldots\ldots\ldots\ldots (b)$$

Let us work this out by an example, taking some of the data given in "Spring's" letter. As his tube is ·625 inside diameter, the spring itself must not exceed ·6 outside diameter, as it must play freely even under a load, which tends to enlarge the coils. As, furthermore, the length of the spring when open is to be 10in., probably 40 coils would be a convenient number. To complete the data, let us assume that the wire is exactly $\frac{1}{10}$in. in diameter; we have, therefore—

$$D = \cdot 1 \qquad R = \cdot 25 \qquad n = 40$$

and we require W and M. By the formula (a)—

$$W = \frac{180{,}000 \times \cdot 1^4}{40 \times \cdot 25^3} = 28{\cdot}8$$

that is, the spring will compress at the rate of 28·8lb. per inch. As spiral springs deflect equally for equal increments of pressure, the weight that will deflect it any other distance is easily found. Thus: 14·4lb. will deflect it $\frac{1}{2}$in., and 57·6lb. 2in. But now let us apply formula (b) and see how far we may go in compressing our spring—

$$M = \frac{12{,}000 \times \cdot 1^3}{\cdot 25} = 48$$

that is to say, 48lb., corresponding to a deflection of 1·66in., is the most we should put on the spring. A heavier wire would give a greater stiffness; but the spring would have less range, other things remaining as they were.—W. J. R.

[61463.]—**Propulsion of Weight.**—I am afraid it is out of my power to give "W. G. G." all the information he wants. But to find the power necessary to propel a bird through the air we had better make a model and find the resistance of the air at different speeds (just the same as for a balloon shaped like a bird), and the power required will, of course, be proportional to the resistance. As to what power a man and horse use to propel themselves without doing other work, I think that can hardly be calculated, because they have to overcome the resistance of the air and the friction of their joints under the weight of their bodies (the latter is, of course, indeterminable).—ELAG.

[61464.]—**Iodine.**—The following is the process generally employed for the extraction of iodine from seaweed. Seaweed, when dried and ignited, yields an ash termed technically "kelp" (all the soda of commerce was previously obtained from this), from which the iodine is obtained. The sun-dried seaweed is incinerated (reduced to ashes by combustion) in shallow excavations at a low temperature, for, if the temperature was allowed to rise too high, a considerable quantity of iodide of sodium would be lost by volatilisation. The half-fused ashes or kelp which remains is broken into fragments and treated with boiling water, which dissolves about one-half of the ash. The liquid thus obtained is evaporated, when, on cooling, the more crystallisable salts separate—viz., sulphate and carbonate of soda, with some chloride of potassium. The mother-liquor still contains the iodide of sodium, sulphide of sodium, and some carbonate of soda. This liquor is then mixed with about one-eighth of its bulk of sulphuric

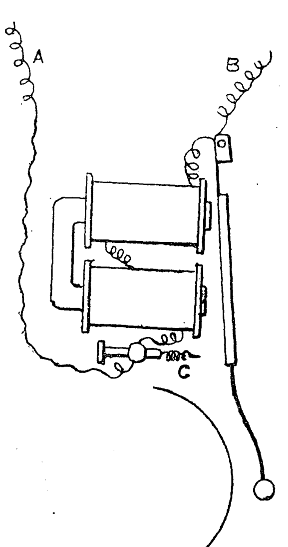
acid, and allowed to stand for twenty-four hours; carbonic and sulphurous acid, and sulphuretted hydrogen gases escape, a fresh quantity of sulphate of soda crystallising out, mixed with a precipitate of sulphur. The supernatant (that which floats on the surface) acid liquor is then transferred to a leaden still, to which is adapted a double tubulated leaden head, luted on with pipeclay; it is then heated to 140° Fahr., when binoxide of manganese is added. The temperature may be gently raised to 212° Fahr., but not higher, as some chlorine would come over and combine with some of the iodine, forming chloride of iodine. The iodine is condensed in spherical glass condensers, each having two mouths opposite to each other, and inserted the one into the other, the end one being fitted to the neck of the leaden head. The iodine is purified by sublimation, heated into a state of vapour, which on cooling returns again to the solid state. The above is an extract from Ure's "Dict. of Arts, &c." I would recommend "Jona" to read the article in extenso. I would further advise him to consult Watts' "Dict. of Chem.," Vols. III., VI., VII., and VIII. The latter part of his query I must leave to someone else.—WILHELM HEINRICH KOPE, Birmingham.

[61468.]—**Brass Surface.**—Perhaps the following may solve the above query:—After the article you wish to "cloud" has been finished, go over it with a piece of water-of-Ayr stone, in order to effectually remove any scratches which may be left from the emery or file, and it serves to dull the surface of the brass. Now procure a piece of cutting charcoal, and file one end flat, dip into water, and by curling it round and round in all directions, the clouded surface is produced. The next thing to be used is a piece of slate-pencil brought to a point. This must also be used with water, to make it cut, and is made to produce a series of small rings, which must not be done with any regularity, but indiscriminately in all directions. This done, then lacquer according to taste.—C. MC J. VILLA RUPRECHT.

[61474.]—**Silver Cell.**—Chloride of silver cells give very little current when first set up. The reason of this is because the chloride has so high a resistance. In action the chloride is reduced to metallic silver, and until a thin film is formed the current is very small. Previous to connecting up just short-circuit for ten minutes. E. Conry is totally wrong when he talks of chloride of zinc being "useless because it has taken up all the zinc it can hold." This is so stupidly absurd it scarcely requires contradiction. If sal-ammoniac is used it should be exceedingly weak. It is not at all necessary to fuse the chloride of silver, it can be used in a powder just as well.—C. D. R.

[61499.]—**Storage.**—Mr. Conry has, I am afraid, mistaken my query. At any rate, his answer wanders a little from the point. If he will be good enough to read it again, I think he will see his mistake.—IOTA.

[61504.]—**Double Electric Bells.**—TO MR. R. T. LEWIS.—It is probably obvious to the querist that the instructions so frequently given as to wiring electric bells so as to ring two or more



simultaneously from the same push, refer solely to those of ordinary construction, in which the line circuit is completely broken at every stroke of the hammer; but in the case of bells made to work without breaking the main circuit it is, no doubt, equally clear that the proper method of wiring must be in series. It is easy to adjust the double bells in this way by setting the contact springs so that they shall always touch either one side or the other. How many of them will then ring together in series is only a question of sufficient battery power to overcome the resistance interposed by the fineness and combined length of the wire upon their coils. I have not had the advantage of seeing the description of the bell to which you refer; but I send herewith an outline sketch of a very simple arrangement devised about the year 1871 by Mr. Moseley which appears to meet your requirement for "ordinary trembling bells which will work together in series." In this bell, supposing the current to enter at A, it would pass through the bobbin coils with usual effect, regaining the line at B. But the armature, on being attracted by the electro-magnet, comes into contact with the point of the coiled spring at C, causing the current to be short-circuited through the armature; thus, although it is by this means cut off from the coils, it is not interrupted in the main circuit. These bells were used for working in series with vibrating indicators of precisely similar construction; but from conversation with Mr. Moseley at the time, I found that the chief object he had in view was the elimination of the induced currents which traverse the wires at every make and break of the circuit, and he argued that if he could produce a bell which would vibrate effectively whilst maintaining an unbroken current in the line wire, he should get rid of these induction effects, which occur twice during every stroke of the ordinary bell hammer. I remember that I was not able to recognise any practical disadvantage arising from induced currents in a well platinised bell, neither could I agree entirely with him that they were due to the making and breaking of the circuit apart from the magnetisation and demagnetisation of the cores (which took place also in his own bells); but for all this I must confess that on experimenting with one of his bells at the time, and also again to-day, I was unable to detect the least sign of an induction spark at the point C, where I should expect to see it every time the current was shunted to and from the coils.—R. T. LEWIS.

[61511.]—**Dynamo.**—1st. It would light six 10c.p. lamps of 40 volts and 1 ampère, the leads generally absorbing the extra E.M.F. 2nd. A gas-engine of 5 or 6 man-power would work your machine if it has a high efficiency; but you would do better with a 1H.P. gas-engine. 3rd. Attach a fly-wheel as heavy as possible to the gas-engine to avoid fluctuation of the lights.—IOTA.

[61511.]—**Dynamo.**—(1) The number, &c., of lamps that your dynamo will light depends on the sorts of lamps. It will light one 100c.p. at 45v. and 6 amps, or four 20c.p. at 45 volts., arranged in parallel, or four pairs of 20v. 10c.p. lamps, each pair being in series, and the 4 pairs in parallel, or 4 lines, each of four 10v. 5c.p. lamps, each line being in series, and the 4 lines in parallel; but you would find the second or third arrangements the only ones of practical utility, because 100c.p. lamps, unless in peculiar positions, waste part of their light by too much concentration, and, on the other hand, putting more than two incandescent lamps in series means, generally, laying up a store of vexation and expense for the future. Even the 2in. series arrangement is distinctly inferior in general utility to the unmixed parallel. (2) The smallest gas-engine made would do for you, as you would only require ½H.P. on the crank-shaft or pulley, or flywheel of the engine. (3) A flywheel is not usually put on dynamos, "discs" being more in use for these. A flywheel on your engine, however, would be eminently desirable, and the larger and heavier the better, for of all engines the gas-engine is the most irregular in its impulses. Even though the additional power required for a fly-wheel should make a sensible difference in the coal bill (and only a ponderous flywheel will do this, for the extra power required by a flywheel is much less than most people imagine), such extra cost will be more than compensated for by the longer life your lamps will have if you use the flywheel, not to mention the much better appearance of the steadier light. "Jumping" incandescent lamps are very trying to the eyes of anyone reading or writing, or doing fine work by their light. The cost of a single lamp would be more than the cost of the extra power required by even an unusually heavy flywheel in three months. (4) and (5) I must answer through the post.—EDWARD CONRY.

[61514.]—**Lining for Accumulators.**—Marine glue applied hot. As good a way as any is to melt the glue and thoroughly warm the cells, pour the glue into them, and empty it out again, leaving a coating of about $\frac{1}{16}$in. inside. There is not the slightest occasion for you to write to E. Conry or anyone else. If, as he says, he is unable to answer through these columns, he certainly cannot do so by letter. The query columns are not intended for gratuitous advertisements, but for general information, and if replies will not bear scrutiny, they are not worth much.—C. D. R.

[61518.]—**Gas-Engine.**—The statements made in the book as quoted in this query are quite correct. The author is describing a type of engine working between fixed limits, where the hotter the sides of the cylinder the greater heat would the gases have at the moment of opening the exhaust valve, and a greater quantity of heat would be rejected in the discharged gases. The sides of the cylinders are much hotter than the temperature of the discharged water, and 100° C. is not too high a temperature to assume considering that in some gas-engines the temperature of the gases at the opening of the exhaust is as high as 1,000° C. The higher the temperature of the water leaving the cylinder jacket the greater the economy in gas consumption. D. Clerk found in his experiments with an Otto engine an economy of 10 per cent. with the water being discharged from the jacket at the boiling point, compared with a quantity run through and the cylinder kept cold. It is better to pay reduced gas bills than increased charges for water, as suggested by E. Conry; and I am yet to learn that gas-engines are usually made lighter than steam-engines; was under the impression that it was the opposite way.—R. A.

[61519.]—**Mechanical Piano-Playing.**—"H. S. M." wishes to make an instrument to play the piano with paper bands. I will send instructions how to make one to fix under the keys permanently, so that it will not have to be taken away when you want to play yourself.—SANDERSON.

[61523.]—**Bell Circuit.**—Yes, earth can be used as return if good connection is made. The best way is either to solder a wire to the gas or water-pipes at each end, or to bury two copper plates of about 4ft. square in coke and damp earth, one at each end, and take an insulated wire to bell. The plates at each end must be made of the same material. For long circuits, however, a return wire should be used, unless battery power is plentiful; but the return need not be insulated, as bare No. 16 works well as earth.—IOTA.

[61527.]—**Agar-Agar Cell.**—I do not know if the Agar-Agar cell has been described before; but if not, perhaps querist may find following useful. The cell consists of a porcelain or glass tray about 1in. deep, having a sheet of silver lying at the bottom, and a copper wire riveted to it as an electrode; above this some lumps of silver chloride are placed, and then a paste of Ceylon moss containing 2½ per cent. of NH_4Cl is put on top of the AgCl. On the top of this again rests a cast zinc plate, unamalgamated, with an electrode. A pile of these cells makes a convenient testing, or, as it is called, potential battery. If made larger, they will work a small lamp; but the capacity in ampère hours is generally rather small. About 1¾ ampère is the heaviest current even a large Agar cell can yield.—IOTA.

[61528.]—**Seeds for Micro. Objects.**—"ERRATUM."—The first name given in my list should be Collomia, not *Collinsia*.—S. BOTTONE.

[61529.]—**Mathematical—Measurement of Drums.**—In working out the formulæ relating to drums, I now find that I made a mistake in considering the number of turns of rope in each layer $= \frac{h}{t}$. Except when there is but one turn in a layer (which is never the case with an ordinary drum) the number of turns $= \frac{h}{t} - \frac{1}{2}$. The following are the corrected equations:—

$$l = \pi \cdot \frac{2h - t}{8t^2}(e - d)(e + d - 2t) \quad \ldots\ldots\ldots\ldots (1)$$

$$e = t + \sqrt{(d - t)^2 + \frac{8t^2 l}{\pi(2h - t)}} \quad \ldots\ldots\ldots\ldots (2)$$

$$h = \frac{t}{2} + \frac{4t^2 l}{\pi(e - d)(e + d - 2t)} \quad \ldots\ldots\ldots\ldots (3)$$

As the centre-line of the rope really lies in a helix, and not in a series of circles round the barrel, the exact value of l is a trifle greater than that here given. In the values of e and h, the errors resulting from considering (for simplicity) each turn to be a circle are generally inappreciable.—J. R. CAMPBELL, Charing, Kent.

[61533.]—**Speed Wheels.**—In Germany makers supply their lathes with a table of all the threads possible with the change-wheels given. Could not English makers do the same? It saves a world of trouble.—A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61541.]—**Brush Polish**—Should be made with French polish and best brown hard spirit varnish. Apply with a camel-hair brush, evenly, avoiding going back over the work, and it should be done in a warm and dry atmosphere or it will become "milky."—T. R. H. S.

[61542.]—**Clock and Sundial.**—Taking the advice of "H. A.," which I find I needed more than the querist, instead of finding "Lockyer to be right," I have to retract the admission that his first clause was true. If fairly quoted, it is the exact reverse. Instead of the dial gaining most on the clock when the sun is in perigee, that season

(or our mid-winter, when he is at the southern tropic) is just when it loses most. At our mid-summer (near apogee) it also loses, but less, and during fewer days; and during more than three months of spring, and more than three of autumn, it gains. I hurriedly trusted Lockyer to begin right in my reply p. 506; but after the word "true" (which should have been the opposite), all my later terms need reversing. The causes of "equation of time" (or difference between dial and clock) are two. The chief or more efficient is the obliquity of the equator to the ecliptic, which, acting alone, would make a half-yearly inequality, or one repeating all its changes twice a year. The other cause, the orbit's eccentricity, has a less effect, but whose period is annual. Lockyer, if rightly quoted, sought to simplify by omitting one of these; but omits the larger, the half-yearly, and not only confines his explanation to the smaller, but inverts the effect of that! The fact of the sun's eastward motion along the ecliptic being fastest in January, makes his westward passage relatively to the dial then slowest, even slower than at the opposite season, July. But because a degree of the ecliptic near either tropic tells for more than a degree of R.A., the solar hours must, at either of them, be longer than average ones. The excess of a solar over a sidereal hour must plainly be greatest then, and be smallest at the equinoxes, where those degrees of the ecliptic that cross the equator tell for less than degrees of R.A. In all states of the orbit, and even if it were circular, the dial must gain in spring and autumn and lose in summer and winter.—E. L. G.

[61548.]—**Ship-Building.**—No; my query was not intended to be funny, by any means. Indeed, had I not known the "E.M." was not a comic paper, I should have thought that "Video" was the man in motley trying to make a ponderous joke. I allude, of course, to the boring out of stern-tube previous to insertion of tail shaft, and immediate preparations for launching of an iron or steel steamer of, say, 3,000 tons—though why size or material should be specified, unless different systems are adopted for every size and material, I fail to see. To a man capable of answering the question, my query contained all that was necessary. —NOVICE.

[61550.]—**Interest.**—The formula in this question ought to be—

$$P = A \cdot \frac{R^n - 1}{(R-1)R^n}$$

and then we have the general equation—

$$R^{n+1} - \frac{A+P}{P} \cdot R^n + \frac{A}{P} = 0 \ldots\ldots\ldots\ldots \quad (1)$$

in which R is the unknown quantity, and being of the $n + 1$th degree there is no known direct method of solution; but we may approximate to the value of R by adopting suitable formulæ. For a first approximation, assume—

$$R_1 = 1 + \frac{A}{P}\left\{1 - \left(\frac{P}{A+P}\right)^n\right\}$$

$$\text{or—} \quad r_1 = \frac{A}{P}\left\{1 - \left(\frac{P}{A+P}\right)^n\right\} \ldots\ldots \quad (2)$$

Then equation (2) gives a fair approximation to the rate. Formulæ, however, could be given if necessary for a nearer approximation; but the labour involved would be about double that which is required in this. For a numerical solution, taking the numbers given in the question—namely, $P = 100$, $A = 7$, and $n = 40$, equation (1) becomes—

$$R^{41} - 1{\cdot}07\,R^{40} + {\cdot}07 = 0 \ldots\ldots\ldots\ldots \quad (3)$$

From eqn. (2) $\dfrac{P}{A+P} = \dfrac{100}{107}$

$$\therefore \text{Log.} \left(\frac{P}{A+P}\right)^n = 40\,(\text{log. } 100 - \text{log. } 107)$$
$$= 40\,(2 - 2{\cdot}029383)$$
$$= \bar{2}{\cdot}824648$$
$$= \text{log. } {\cdot}06678$$

$$\therefore 1 - \left(\frac{P}{A+A}\right)^n = 1 - {\cdot}06678 = {\cdot}93322$$

$$\text{and } \frac{A}{P}\left\{1 - \left(\frac{P}{A+P}\right)^n\right\} = {\cdot}07 \times {\cdot}93322$$

$$\therefore r_1 = 0{\cdot}0653247$$

and 1·0653247 substituted in (3), for R ought to satisfy that equation. Computing from this the powers of R we have—

$$(1{\cdot}0653247)^{41} = 13{\cdot}389$$
$$(1{\cdot}0653247)^{40} = 12{\cdot}584$$

$\cdot07 \times (1{\cdot}0653247)^{40} = 13{\cdot}46488$, and eqn. (3) then becomes—

$$13{\cdot}389 - 13{\cdot}46488 + {\cdot}07 = -{\cdot}00588$$

hence the required interest will be 6·53247 per cent.—MILVERTON.

[61551.]—**Flow of Water through Pipes.**—Thanks to "Elag" for his formula, which, however, scarcely seems to answer my question, for applying his rule to the case given—viz., a 24in. pipe 100 yards long, inclination 1 in 100. For an inclination of 1 in 20, a pipe $3\frac{1}{2}$in. diam. would be required to take the same water, which scarcely seems possible. If I am wrong in my application of his rule, will "Elag" kindly work out my given instance fully?—ST. GEORGE.

[61560.]—**Engineering.**—One would require to be intimately acquainted with the whole circumstances before expressing a very decided opinion. It is possible to be too harsh with pupils, but, speaking generally, I should say that those who are anxious to learn will always have abundant facilities for learning, not by making themselves busybodies and hindrances about the works, but by getting information through the proper channels. I have often had to order pupils to their benches, not because they were trying to obtain information, but because while ostensibly so doing they were idling their own time, and hindering workmen as well, yet I dare say they have thought themselves harshly dealt with. Many pupils are a nuisance and a plague in the shops. The mere premium is as nothing in comparison with the disorganisation, trouble, and waste which they might cause if allowed to do as they please. My idea of pupils is that in every case they should have no privileges above those of the apprentices who pay little or nothing, save that of going through all the departments in turn, which is privilege amply sufficient. I very much doubt if any pupil is much benefited by making notes while in the shops. He who works hardest, keeps his time, chips, files, and turns, educates his eyes and hands to the best of his ability, and gives his whole attention to the department in which he happens to be at the time, is the one who makes his mark afterwards. A pupil, like an apprentice, has golden opportunities before him, and if he does rough, and dirty, and distasteful work well, he is certain to get the best work in time, for the simple reason that it pays to give the best work to those who can do it best. The shop training is the most important part of the pupils' work, affording opportunities which, if wasted, never return again. There are plenty of employers, plenty of draughtsmen, who daily regret having missed the opportunity of knowledge afforded by the work of the shops. Even if rules and regulations do sometimes appear harsh to those newly entering a factory, it should be remembered that only by a system of discipline can the work of a large factory be carried on. The interests at stake are too heavy to allow of their being affected by the recognition of a privileged section, whose only claim is that of being gentlemen. There is no room for gentlemen, in the sense of non-workers, in a factory.—J. H.

[61562.]—**Mechanics.**—Momentum of one body $= 4 \times 12 = 48$, and of body moving in opposite direction $= 8 \times 4 = 32$. Momentum lost by first body at end of compression $= 48 - 32$, and the common velocity at that time would be $\dfrac{48-32}{4+8} = \frac{4}{3}$ in same direction of fastest moving body, which has, therefore lost $4 \times 10\frac{2}{3}$ of momentum. The coefficient of elasticity being 0·5, the whole momentum it loses is $\frac{3}{2} \times 4 \times \frac{32}{3} = 64$; $\therefore \dfrac{48-64}{4} = -4$ its velocity; that is, it rebounds with a velocity of 4. The momentum lost is imparted to the body which has a momentum of -32; $\therefore -32 + 64 = 32$, and $32 \div 8 = 4$; that is, a rebound with a velocity also $= 4$, as (its velocity being in opposite direction to the other body before impact) its first velocity had a negative sign.—T. C., Bristol.

[61562.]—**Mechanics.**—Let the velocities of the two bodies at the end of the impact be v_1 and v_2, the velocities before impact being 12 and 4, and their masses 4 and 8 respectively. Then the velocity lost by the first will be $12 - v_1$, and that gained by the second will be $v_2 - 4$. Hence, the momentum lost by the first will be $4\,(12 - v_1)$, and that gained by the second will be $8\,(v_2 - 4)$. But in direct impact the momentum lost by one body will be equal to the momentum gained by the other.

$$\therefore 8\,(v_2 - 4) = 4\,(12 - v_1).$$

Or—

$$v_1 + 2v_2 = 20 \ldots\ldots\ldots\ldots (1).$$

Again, since the relative velocity of the two bodies before impact is $12 - 4$, and that after impact is $v_2 - v_1$. And since by experiment it is found that in direct impact the relative velocity of two imperfectly elastic bodies after impact bears to the relative velocity before impact a constant ratio, called the coefficient of restitution, in this case equal to ·5, we have—

$$\frac{v_2 - v_1}{8} = {\cdot}5$$

Or—

$$v_2 - v_1 = 4 \ldots\ldots\ldots\ldots (2).$$

Therefore, from (1) and (2),

$$v_1 = 4, \text{ and } v_2 = 8.$$

Or the bodies will be moving in the same direction with their velocities interchanged. But if the bodies meet each other in opposite directions, by a similar method it will be found that

$$v_1 = -4 \text{ and } v_2 = 4,$$

or each of the bodies after impact will have changed their directions, and will be moving with equal velocities.—MILVERTON.

[61563.] — **Torricelli's Theorem.** — In my answer in your last issue I took in mistake Q = amount of discharge per sec., instead of per minute, as the other amounts were expressed. The following is correct:—

$$A = \frac{Q}{E} = \frac{{\cdot}133}{963 \times {\cdot}62} = \frac{{\cdot}133}{597{\cdot}06} = {\cdot}00022 \text{ sq. feet.}$$
$$= {\cdot}03168 \text{ sq. inch}$$
$$\therefore \text{Dia.}^2 = {\cdot}0403 \text{ inch}$$
$$\text{Dia.} = {\cdot}2007 \text{ inch.}$$

—ELAG.

[61563.] — **Torricelli's Theorem.** — In the answer I gave to this question, by some mistake the flow has been taken for three minutes instead of for thirty minutes. For thirty minutes the equation would be—

$$1{,}800\ V\ A = 4 \text{ cubic feet.}$$
$$\text{or} \quad A = \frac{4}{16 \times 1{,}800} \text{ square feet.}$$
$$\therefore \quad A = {\cdot}02 \text{ square inch.}$$

and the area of the orifice would be ·032 square inch.—MILVERTON.

[61565.]—**Daniell's Battery.**—I can ring two bells in parallel for nearly an hour twice a day with four No. 1 Leclanchés in series. It is true a Daniell beats a Leclanché for constancy; but even Leclanchés can keep a bell ringing for a long time, if properly attended to. The principal fault in the Daniell's battery is the amount of attention required; but the porous pot can be prevented from becoming so brittle by means of paraffin wax. If the top for about 2in. be steeped in boiling paraffin wax, the crystals stop forming round the edge. The principal cure is plenty of attention, and keeping them in a cool, dry place.—IOTA.

[61569.]—**Violin-Maker.**—Grand-Gerard was a maker who worked in the Vosges about the end of the 18th and beginning of present century.— W. A. K.

[61574.]—**The Calculus.**—I have never seen Ritchie's book on the "Differential Calculus," but I venture to think "Tyro's" difficulty may be cleared up as follows: If u be a function of a variable quantity x, and x be supposed to increase, the rate of increase of u with respect to that of x is expressed by the differential coefficient $\dfrac{du}{dx}$. This important fact is explained in all modern works on the differential calculus. Now the area of a square is a function of the side, so that if the side $= x$ we may put $u = x^2$. But the differential coefficient of x^2 with respect to x is $2x$. This means that the area of the square increases $2x$ times as fast as the side x. The rate of increase varies with the value we choose to assign to x. When x = 10ft., the area is increasing at 20 times the rate x is increasing; and since x is increasing at the uniform rate of 3ft. per second, the area at the moment that x = 10ft. must be increasing at the rate of 20 times 3ft. per second, i.e., at 60sq.ft. per second.—J. R. CAMPBELL, Charing, Kent.

[61574.]—**The Calculus.**—I thank "Weald," "M.I.C.E.," and "M." very sincerely for the trouble they have kindly taken to remove my difficulty with respect to the fundamental idea of the calculus. If I could have found in any of my books the numerical illustrations they have given, I should have been saved immense trouble and loss of time. Most writers on the calculus warn their readers that they are about to enter on new lines of thought, and that they will meet with difficulties which they must not expect all at once to overcome. It surprises me that these authors do not endeavour, by means of familiar and numerical examples, to assist students to overcome the difficulties of the subject. Is it that these matters are left for the explanations of tutors? or is it that the writers have forgotten the steps by which "the rough places were made plain" to them? I have not the advantage of a tutor; but have all the aid which the possession of the best books on the subject, both English and American, can give. Yet I am often confronted with difficulties of which I find no notice in my books. As I said in my former communication, I accept what I cannot understand, and pass on, returning to the difficulty from time to time. But I am not content to accept without understanding. By repeatedly returning to a subject I sometimes find my way out of a difficulty which has long troubled me; but in some cases, even after long application, I have failed. As the same difficulties probably beset others, who, like myself, cannot consult a tutor, it may not be amiss if I give another example of these difficulties. In most treatises, after the rules for differentiating simple functions have been explained, the subject of successive differentiation and the development of functions into series is

introduced, and this without any preparation or explanation. The process of successive differentiation is simple enough. I do not think it would be difficult to construct a machine for effecting it; but the *meaning* of it I am afraid I have not succeeded in understanding. My difficulty is this. I will take a very simple example. Given $y = m x^2$ we have $\frac{dy}{dx} = 2 m x$, by which expression we virtually say that the rate of variation of the function y is to the rate of variation of the variable x as $2 m x$ is to unity. All this is clear enough, the function and variable are real or concrete quantities; but $2 m x$, the derivative or differential coefficient, is not a concrete quantity, but a ratio. We are directed to treat this ratio by differentiating it, and thereby obtain a new derivative or differential coefficient; and if x had appeared in the third, fourth, &c., power in the original derivative, we are directed to repeat the process until x disappears, and the expressions thus obtained are the second, third, &c., derivatives. I can understand treating a function by the process of differentiation, and thereby determinating the ratio which its change bears to the changed and the variable entering into it; but what the meaning is of treating the ratio again and again in the way in which we treated the original function I cannot understand. In other words, I can understand differentiating a real quantity (the function of a variable quantity); but I cannot understand the differentiating of an abstraction, that is a ratio. What I intended saying about series I will defer, and will conclude by again thanking the correspondents who replied to my last communication.—TYRO.

[61575.]—**Indicator.**—This engine appears to be working with a high grade of expansion, and therefore very subject to condensation. I would suggest that a portion of the steam is condensed, and so a larger quantity is required to do the same work, and some of it is turned into condenser as hot water, so raising the temperature of well. Could you not try the engine one day with jacket on and one day off, and notice quantity of feed-water and fuel supplied to boiler each day, and let us know the result?—T. C., Bristol.

[61577.]—**Meridian Instrument.**—TO "HERMES."—You should buy the book descriptive of the instrument at Dent's, 61, Strand, the price of which is 1s. or 1s. 6d. It must stand on a perfectly level plane, say of brass, cemented or run with lead on to a stone slab, and this plate need only be about 4in. square. Near one edge, which must point nearly or quite due north and south, is a strip of brass like a flat ruler, held down by two or three screws, and with a trifling range of adjustment, so that when the side of the instrument is merely placed in contact with the strip it is perfectly in position for all time, and does not require fixing at all. As to its use, read the book, and if there is anything that requires further explanation, I think I can tell you all you want. Baker, in Holborn, has, or had, some time since two or three more or less elaborate ones for sale second-hand. I knew of one of the universal pattern fitted with spirit-levels and telescope, and arranged to read at any hour from 9 a.m. to 3 p.m., that sold at Stevens's a few months ago for £1; but then that was a universal one, of use only to a traveller. I think plain ones second-hand would cost about as much as that. If you get one, do not take it to pieces to examine it, and you had better get it placed in position by the maker, as you will, or, at least, I did, find it almost a wearisome job getting it back into adjustment, and properly fixed as to the south point. Of course, you will fix it where you are most likely to be at noon to read it.—J. K. P.

[61581.]—**Telephone Switch.**—It can be done, I know, for it has been done in a particular installation with which I am acquainted; but it is a complicated and difficult arrangement. At the time a manager of a telephone company made a considerable bet that it could not be done, and lost. I think I have the diagrams somewhere, and will look them up and let you know next week.—EDWARD CONRY.

[61583.]—**Castings.**—The metal is only tin solder cast in iron or gun-metal moulds.—A. F. SHAKESPEAR, Lüttichaustr. 14, III., Dresden.

[61583.]—**Castings.**—The alloys used in making toys belong to the pewters and the type-metals, and therefore include those composed of tin and lead, and lead and antimony; of tin, lead, and antimony; lead, antimony, and bismuth, and Bibra metal, which is excellent for small casts, and consists of bismuth 6, tin 3, lead 13, but is too expensive for toys. The moulds are of plaster or iron.—SAML. RAY.

[61585.]—**Polishing Fretwork.**—There is just a possibility that the work appears cloudy from the presence of the oil, which can be removed with a few drops of spirits of wine on a clean rubber; or perhaps the first coating has been entirely absorbed by the wood. Be careful not to use too much oil. One drop at a time is sufficient, and that is to prevent the pad from "sticking."—W. HOLDER, Newport, Mon.

[61585.]—**Polishing Fretwork.**—For small work like this I find there is no better plan than to give a very slight coating of linseed oil, and then put on French polish (using a little oil on the face of the rubber) until the wood is filled, then let it stand till next day, when you can go over with a clean rubber and some good polish, finishing with a little methylated spirit to take up surplus oil, and so leave face of polish with good gloss. Be careful not to use more oil than is just necessary to make the rubber slide easily over face of work. I generally get the edges as clean cut as possible, and oil them only.—WOODWORKER.

[61586.]—**Waterwheel.**—The fall of 10ft. before it gets to the wheel is simply power lost. The power in wheel = 14 × 10 × 3 = 420ft.-lb. per minute gross, or, say, 300ft.-lb. effective per minute. Nett power required, 1,000 × 10 × 100 ÷ (24 × 60) = 700 per minute without friction of pumps and pipes. From this you will see you have only one-third the power required.—T. C., Bristol.

[61588.]—**Brass-Cleaning Composition.**—This is probably some composition containing oxalic acid, which is a well-known agent for cleaning brass. The following will clean either brass or copper:—Oxalic acid, 1oz.; rottenstone, 6oz.; gum arabic, ½oz.—all powdered up. Then 1oz. of sweet oil and sufficient water to make a paste. Apply a little, and rub dry with a piece of flannel or soft leather.—W. HOLDER, Newport, Mon.

[61589.]—**Coal Economy.**—I have by anticipation answered the query of "Cane Sugar," for all that can be said, unless specific questions are put, is that improved appliances for saving coal should be used. It is usual to call in a "consulting engineer," whose fee may range from five to fifty guineas; but if "Cane Sugar" will give me the requisite statement of conditions, I will endeavour to help him gratis. It is no use talking of "vials of contempt," whatever they may be; what is wanted are solid facts, and I cannot find one in your correspondent's remarks—not even a question on a matter of fact. He seems to adopt the statement that 900 tons of coal is a suitable quantity to use in refining 1,800 tons of sugar. If that is so, it is time it was altered. I have some knowledge of Christian-street, E., and the purlieus of the Commercial-road, and I know that in sugar refineries steam is used for other purposes than driving engines; but I do not gain much light from the solitary fact given by "Cane Sugar"—that he knows a refinery working about 400 tons weekly, in which 130H.P. is used. Presumably this is 400 tons of sugar; but how the 130H.P. is arrived at is not quite clear. Supposing, however, the 130H.P. represents machinery, that ought to be obtained at an expenditure of 4lb. of coal per I.H.P., so that one ton would yield the required H.P. for four hours (I use round figures, with every allowance), or 6 tons per day of 24 hours—i.e., 42 tons per week of 168 hours, and it is not easy to work more hours in a single week. "Cane Sugar" omits to give the quantity of coals consumed; but perhaps he will supply that and other interesting data. At all events, he must, before he can reasonably expect me to devote time in the endeavour (perhaps thankless) to show him and others how they may save money. He need not go far amongst makers of steam-engines and experts generally to learn that when anyone suggests to a manufacturer the advisability of adopting appliances more economical in fuel than the plant at work, the answer is usually, "Hang the coals; they are cheap enough. I am not going to lay out more capital in the hope of saving coals." I am sorry I cannot say anything more definite; but I think it will be tolerably obvious that each case must be taken on its merits with a full knowledge of the surrounding conditions. I have stated what "Cane Sugar" should get his 130H.P. for, and it remains for him to supply further data.—NUN. DOR.

[61595.]—**Lead Burning.**—If you are dexterous with the soldering iron you can do it with this. The usual way is with a blowpipe flame and a little hammer; but the operation requires considerable skill of hand.—EDWARD CONRY.

[61599.]—**Gunmetal.**—Melt separately 1lb. copper and 2oz. tin. When melted mix.—A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61599.]—**Gunmetal.**—Tin 1, copper 8, and 1½lb. per cwt. of zinc added, and the alloy should be melted twice to insure sound castings. There are numerous other proportions.—W. HOLDER, Newport, Mon.

[61599.]—**Gunmetal.**—First melt the tin with twice its weight of copper, and then add it to the proper proportion of melted copper. Exclude oxygen as much as possible from the melted alloy, and well mix with a wooden stirrer, as gunmetal has a tendency to separate into two parts by reason of the very different specific gravities of the two metals. It should be run into the mould at a temperature as little above its melting point as possible, for the same reason. A little more tin than is necessary should be added to allow for the tin oxide which is sure to be formed in spite of every care, and should be skimmed off before casting. The addition of some old gunmetal aids the formation of the alloy.—M. ISADER, Lewes.

[61600.]—**Cone of Lathe.**—This is such a small affair that I would recommend querist to turn a cone of wood, say, 6in., 6½in., and 7in., and turn in position, if required, to suit tension of band on various speeds.—T. C., Bristol.

[61601.]—**Decomposition of Carbonates.**—Carbon would be formed by heating a carbonate to a moderately high temperature in hydrogen; but carbon and hydrogen only combine directly with one another at the extremely high temperature of the voltaic arc.—M. ISADER, Lewes.

[61603.]—**Reduction of Numbers.**—In dealing with large numbers, it is customary to use the index notation—that is, to use the first 4 or 5 figures, and multiply by the necessary power of 10. Thus, the velocity of light, 300,000,000 mètres per second, is written 3×10^8; the distance between earth and sun is $1{\cdot}487 \times 10^{13}$ centimètres, and so on. In the index notation it is usual to divide the number in such a way that the index of the 10 is the characteristic of the log. of the number. Of course, any large number may be reduced by dividing it; but I suppose this would not suit the querist. It is not easy to give a definite reply to this query in the absence of any information as to why logs. are not suitable. If "Reduction" will be more explicit perhaps some method of helping him might be devised—WM. JOHN GREY, F.C.S., Newcastle-on-Tyne.

[61604.]—**Chemical Equivalents.**—I do not know of any tables such as you want being published separately; but any good little book on chemistry, such as Roscoe's "Lessons on Elementary Chemistry," published by Macmillan and Co. at 4s. 6d., will answer your purpose.—M. ISADER, Lewes.

[61604.]—**Chemical Equivalents.**—I am not aware of any book which contains the molecular weights of compounds and water of crystallisation of salts in the form "Vulcanite" apparently requires. The atomic weights of the elements are always given in even the most elementary works on chemistry.—WM. JOHN GREY, F.C.S., Newcastle-on-Tyne.

[61606.]—**Railway Fish-plates.**—The system of uniting the ends of the rails by fish-plates was introduced in 1847. Previous to their introduction the rails were placed one against the other in a chair made of extra size for the purpose, called a "joint chair," there being no rigid connection between them. The advantage in having iron plates uniting the ends of the rails together, by being placed on each side of the web of rails and bolted firmly to them, is that it is impossible for the one rail to rise slightly above the other while a train is passing over them.—AMATEUR.

[61609.]—**Warming Railway Trains.**—On the Saxon Railway Line steam is used with considerable effect; in fact, one is nearly roasted. Formerly blocks of heated charcoal were used, but they caused danger from fire.—A. F. SHAKESPEAR, Lüttichaustr. 14, Dresden.

[61610.]—**Circular Saw.**—Do not think of an 8in. saw for such "things." Try a 3in. saw, and be contented with that to cut ⅜in. stuff slowly; or, better still, throw the gear away and fit up a proper saw bench as recently described in "Amateur Workshop."—T. C., Bristol.

[61613.]—**Dynamo and Continuous Current Battery.**—Yes, just the same; and if you have the necessary power to drive it, will be a great deal more convenient than the battery.—EDWARD CONRY.

[61613.]—**Dynamo and Continuous Current Battery.**—A well-constructed dynamo (not alternating) will produce precisely the same results.—S. BOTTONE.

[61613.]—**Dynamo and Continuous Current Battery.**—Yes; you can use this exactly in same way. When giving the current and E.M.F. you name, then carry your connections from the terminals of dynamo, and use same for medical work. I presume the dynamo will be shunt-wound.—OHM.

[61614.]—**Clutch.**—I suppose you mean the method of detaching nut from leading screw. If so, two illustrations have already been given—viz., in "F. A. M.'s" lathe, and in "Amateur Workshop." I have two lathes, in one of which a half-nut is moved back or forward by a half turn of a quick thread screw; and the other has a half-nut above and below, and these are caused to separate or approach by having pins on them which take in grooves in a cam plate rocking on a central stud.—T. C., Bristol.

[61615.]—**Porcelain Clay.**—Porcelain insulators can only be made in a porcelain manufactory, where the required machinery for preparing the clay and the necessary convenience for making and ovens for firing them is at hand. "H. T. C." had better make a drawing of what he requires, and send it to an insulator-maker or a porcelain manufacturer, and get them made for him.—O. B. O.

[61616.]—**Gramme Dynamo.**—If the fields be connected to the armature as a shunt machine, then about 8lb. No. 12 will be ample on the armature; but I am afraid you will not get 20 twenties out of the machine if you use a wire ring. I should strongly advise a Pacinotti ring laminated, with teeth.—S. BOTTONE.

[61616.]—**Gramme Dynamo.**—If you can run your dynamo to get 100 volts, then you will require 13 ampères; ·048in. wire will easily carry this on your armature, and you might wind it to a resistance of about ·5 ohm. This would be, say, 450ft. total length on armature; if you can work with a shorter length, then you will have higher efficiency.—OHM.

[61617.]—**Removing Ink Stains.**—A solution of chloride of lime will effect this.—W. HOLDER, Newport, Mon.

[61617.]—**Removing Ink Blots.**—I have not come across the fluid you mention for removing ink blots; but it's ten to one that it is a preparation of potassic oxalate ("salts of sorrel"), or oxalic acid, probably solution of the former.—R. A. R. BENNETT.

[61617.]—**Removing Ink Blots.**—This is probably some solution which slowly evolves chlorine gas. A solution of ordinary bleaching powder ("chloride of lime") in water will effectually remove ink marks from paper, but it must not be too strong, or it will act injuriously on the paper. Experiment will easily determine the proper strength to use.—REYMOND.

[61620.]—**Fixing Laminated Armature to Spindle.**—To S. BOTTONE.—Turn the spindle down, so as to leave a shoulder at the driving end. Run the punchings on the spindle, as shown at page 373 Vol. XLIV. of the ENGLISH MECHANIC. At the commutator end a thread must be cut in the spindle, on which is screwed a nut, which serves to clamp the laminations into their place.—S. BOTTONE.

[61622.]—**Planetary Drawings.**—Why not use black surface-paper, and draw thereon with Chinese white or white chalk?—SM.

[61622.]—**Planetary Drawings.**—I know nothing of the drawings you mention in this unastronomical corner of the world, but have seen very nice backgrounds made with Indian ink. The laying on is the secret. Is "Constant Reader" acquainted with the blue process described in back numbers (774 : 898)? It is said to give beautiful backgrounds, and is highly spoken of by Mr. Brashear.—ARTHUR MEE.

[61624.]—**Speculum.**—"Etanin" says "under the shadow test the curve is certainly parabolic"; but I may tell him the shadow test will not disclose whether it is certainly parabolic or not—in fact, I can assure "Etanin" that "figuring" is much too delicate to be detected by this test without very great experience and extreme patience, and cannot be determined in actual amount at all by the shadow test. The probability is there is too much correction, which would be fatal to good definition of stars and planets, and yet would define the moon very fairly. Such a curve would not, however, give perfect definition of the minute details with which the moon is covered, and which give the chief charm of observing it. "Etanin's" only course is to persevere, reduce the over-correction if possible, and, if not, to fine grind again and re-polish, hoping for better results.—J. C. LINSCOTT, Ramsgate.

[61626.]—**Assaying of Ores.**—If "Cymro" will call between 10 a.m. and 4 p.m. (Saturday before one o'clock), at the Metallurgical Laboratory of King's College, Strand, I or my assistant will be pleased to give him the information he requires. Students whose time is limited may specialise in any subject in this laboratory without being compelled to go through the whole of the usual course; special arrangements can be made as to times of attendance. For those engaged during the day the Laboratory is open on Friday evenings from seven to nine.—A. K. HUNTINGTON.

[61627.]—**Boring Hard Wood.**—I should certainly use a large, sharp twist drill. The centre-bit, though a good and quick tool for rough work, is not a particularly clean cutter, especially for large holes. I should use a twist-drill, and hold your hard wood down on a bit of soft board, so that you can carry the cut a little into the latter each time.—EDWARD CONRY.

[61627.]—**Boring Hard Wood.**—Your centre-bit will bore cleanly if: 1st, it runs true; 2nd, you back the piece being bored by another; 3rd, the thin clearing portion of the bit should be at least $\frac{1}{32}$in. longer than the extreme point of the cutting portion, so as to enter the wood in advance of the knife-edge and just behind the centre point. The effect of this will be to cut out a clean button piece at the end of the boring, and leave the edges smooth.—C. D. R.

[61630.]—**Loss of Power in Model.**—The ratio of power to resistance in crab $= 8 \times 43 \div 149 = 23.1$ nearly. A weight of $56 \div 23.1 = 2\frac{1}{2}$lb. nearly, should keep the weight balanced—more exactly 2·46lb. As it takes 3·1lb. to raise it, there is $3.1 - 2.46 = 0.64$lb. loss, or $0.6 \times 100 \div 3.1 = 21$ p.c. of total loss in friction nearly.—T. C. Bristol.

[61630.]—**Loss of Power in Model Lifting Crab.**—The winch handle has a power of 2·9 over the circumference of the drum, and the wheel work gives 8 to 1; therefore 3·1lb. on winch handle should raise $2.9 \times 8 \times 3.1$lb. on circumference of drum $= 71.92$lb. But it only lifts 56lb., or $\frac{56 \times 100}{71.92} = 79$ per cent. There is therefore a loss of 21 per cent.—ELAG.

[61630.]—**Loss of Power in Model Lifting Crab.**—The power 3·1lb. is applied at the end of a lever $\frac{43}{2\pi}$in. long (since radius = circumference $\div 2\pi$), and is to be multiplied by 8 on account of the wheel work. The weight is wound on a drum, the radius of which is $\frac{14.9}{2\pi}$; consequenly, the power, 3·1lb. should just raise $\frac{43 \times 8 \times 3.1}{2\pi} \div \frac{14.9}{2\pi} = \frac{1066.4}{2\pi} \times \frac{2\pi}{14.9} = \frac{1066.4}{14.9} = 71.5$lb. As, however, only 56lb. were actually raised, there remain 15·5lb. to be accounted for, giving a loss in friction, &c., of 21·7 per cent., or over one-fifth of the total power exerted.—REYMOND.

[61633.]—**Dynamo.**—TO MR. BOTTONE OR MR. CONRY.—You would do well to wind your fields with 30lb. of No. 22 if you desire to convert your machine into a shunt; but I am doubtful whether you will run eight 16c.p. lamps with No. 18 on the armature.—S. BOTTONE.

[61633.]—**Dynamo.**—TO MR. BOTTONE OR MR. CONRY.—Mr. Bottone can probably tell you better than myself what alterations to make, if any successful alteration is practicable with your machine; but I have seldom known any satisfaction got from altering to one purpose a dynamo made for another and entirely different one. I think I may say at once, however, that you cannot possibly with your castings get the machine to light eight 16c.p. lamps by any alteration of wiring. The machine and armature are not large enough; and without entering into calculations, I should certainly consider No. 18 wire far too small for an armature for a current of from 10 to 12 ampères. I think you had much better make up your mind at once to construct a new machine right out.—EDWARD CONRY.

[61634.]—**Will o' the Wisp.**—My mother, on being asked this question, assures me that she saw this phenomenon at the foot of Primrose-hill, London, in 1848.—S. BOTTONE.

[61634.]—**Will o' the Wisp.**—You could see many of them in certain parts of the Fen country (e.g., Lincolnshire), or on the Bog of Allen in Ireland. If I remember rightly, it is merely light sulphuretted hydrogen, and corresponds to the "St. Elmo's Fire" of the sailors that appears at the masthead in storms.—EDWARD CONRY.

[61634.]—**Will o' the Wisp.**—Relatives and friends of mine have seen this curious phenomenon, generally on marsh or moorland—a tiny star, rather than a flame, dancing along. See also Mrs. Watney's account, under heading "Welsh Superstitions," in December number of *Red Dragon*, the national magazine of Wales.—ARTHUR MEE.

[61634.]—**Will o' the Wisp.**—I saw this appearance myself one close, moonless night the summer before last. It was a blue, dancing flame (very much like what children call "Snapdragon"), hovering over a piece of wet ground close to the side of the railway along which I was slowly travelling. I should have thought it was common enough in fenny districts. I was sorry I could not go and examine it.—B. HARCOURT.

[61635.]—**Engine.**—The first thing is, will your work permit of a slightly jerky action of engine owing to the lower speed? If the flywheel is heavy, this would not be felt much. Then do you work the boiler at a good pressure and throttle the steam at the engine? If both cases are "yes," it would be some advantage to reduce speed and not throttle so much, or work at a higher pressure. The engine, however, is so much too large for its work that there would not, perhaps, be a great saving, unless you are using more than 30lb. coal per hour after steam is raised.—T. C., Bristol.

[61637.]—**Dewing of Object-Glass.**—By all means close the end of the dew-cap when work is over. This is best done with a plug made to fit tightly by means of flannel. The dew-cap should have a length three times its diameter, and should fit so tightly on the end of instrument that neither dust nor spiders can gain access. Our object-glass never becomes bedewed when thus shut up, but such an event has happened when observing in cold, damp weather. The moisture is best removed by gently blowing warm air from above a lighted spirit-lamp on to the lens. We always prevent deposition of moisture on metal-work during wet weather by the use of a gas stove.—A. PERCY SMITH, Temple Observatory, Rugby.

[61638.]—**Vertical Boiler.**—Your boiler should stand 80lb. safely, and I should work it at that. With a good draught it should give $\frac{1}{2}$H.P. Run the engine at 250 revs. at least, 300 would be better. Size of hole in safety-valve $\frac{1}{2}$in. diam. I should not have a lever, but a dead weight of 16lb. on valve, and you can proportion lever to give this if you prefer it—say, fulcrum to valve 1in., and total length equal 8in., requiring 2lb. nearly on end.—T. C., Bristol.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Teaching a Poodle to Read.—Lecturing at Walsall the other day, Sir J. Lubbock, M.P., said: That the dog was a loyal, true, and affectionate friend must, he thought, be gratefully admitted; but when they came to consider the psychical nature of the animals, the limits of their knowledge were soon reached. He first began his experiments with a small terrier; but as these dogs were not accustomed to fetch and carry, and as fetching and carrying was part of the treatment, he found it better to find a dog that was accustomed to such work, and he selected a black poodle called "Van." First he took two pieces of cardboard, about ten inches by three inches, and had printed on the one the word "food" leaving the other blank. The card bearing the word "food" he placed over a saucer containing bread and milk, and put the blank card over an empty saucer. Van's attention was called to the saucers over and over again. In about ten days Van began to distinguish between the two cards. Then he put the two cards upon the floor, and signalled to Van to bring one of them, which he readily did. When he brought the blank card he (the lecturer) threw it back with a gesture of impatience; but when he brought the one with the word upon it he was given some bread and milk, and in a few days he distinguished between the two cards. Then he had some cards printed with the words "out," "tea," "bone," "water," printed upon them—others having other words placed upon them, to which he did not attach any importance, merely putting them in that he might have a certain number. Soon Van distinguished between the white and the printed cards, but it took him a long time to recognise the words "out," "bone," "tea," and so on; but at last, if asked if he would go out, he fished out the card with that word upon it from the lot placed higgledy-piggledy upon the floor, his behaviour showing that in bringing it he really was making a request. This was only the beginning, however; but it was suggestive, and might be carried further, although no doubt the limited senses of the dog constituted a difficulty in the case. His wife had a beautiful collie, which was generally in the room when Van was being fed, and who was anxious to be fed in the same way; but it never occurred to the collie, although he saw the operation thousands of times, to pick a card and bring it that it might be fed in the same manner. Then pairs of cards differently coloured were put before the dog, and, one being picked out, an attempt was made to induce the dog to bring the corresponding one, but although two lessons per day were given for three months the dog had no more idea of what he should do at the end than he had at the beginning.

THE capital of 100,000fl. required for the organisation of an International Food Exhibition at Amsterdam has been subscribed. The buildings will cover an area of 6,500 square mètres. An International Exhibition of Popular Food and Cookery will be opened at the end of the present month at Leipsic.

QUERIES.

[61639.]—**Dry-Rot.**—Can any of "ours" give practical advice for cure of dry-rot in interior door jambs and skirtings? House is about ten or twelve years old, and it is not the outer walls that are affected.—T. R. H. S.

[61640.]—**Battery.**—TO MR. CONRY.—I am constructing a large battery. The cells are 12 by 9 by 9, and hold over three gallons each. I intend using a nitrate of soda battery. There are four corrugated carbon plates, 10 by $1\frac{1}{2}$, in each porous pot. The zincs are 12 by 8. Are the proportions of the elements correct? How many ampères may I expect, and what size leads will be required to carry the current?—DENTIST.

[61641.]—**Dynamo.**—TO MR. CONRY.—I have a Siemens H armature dynamo made from Jones's castings. It is $6\frac{1}{2}$in. high; wire space, $3\frac{1}{2}$ by $3\frac{1}{2}$; armature, $3\frac{1}{2}$ by $1\frac{7}{8}$. The fields are wound with 3lb. 10oz. No. 20 d.c.c. wire. The machine is very strongly made. What size wire should the armature be wound with to get the best results as a motor for driving dental drills and burrs with a flexible shaft? Should it be connected shunt or series? I intend using with the above battery.—DENTIST.

[61642.]—**A Good Illuminant.**—Am interested in good lighting. Have seen in daily paper description of an illuminant tried at Marlborough Rooms, London, during past few days, which is called the "Welsbach" light. It is described thus: A special gas-burner, over which is hung, in an ordinary chimney glass, a specially-prepared material in the shape of a doll's skirt, composed of incombustible oxides. It is believed each "mantle" will last six months, and can be replaced for 1s. The incandescence of this "mantle" gives the light. It is described as whiter than ordinary gaslight, nearly as pure and blue as any produced by electricity, and far cheaper than any produced by ordinary gas-burner. Pictures seen as clear as by daylight, clearer than on some foggy afternoons. It is brighter than light of Argand burner, and nearly as cool as a candle. Reduces gas consumption nearly 75 per cent. Name of manufacturing firm not given. I live in country. Could some reader of "Ours" furnish name of firm, and express an opinion of same?—LIKE TO KNOW.

[61643.]—**Boiler Query.**—Of two steam boilers, one at 45lb. pressure and the other at 65lb., which would be the hottest? If a 2in. valve was opened into a cistern containing cold water, which would keep the water at the highest degree of heat?—ENQUIRER.

[61644.]—**Albategnius.**—Described by Webb (289) as "a walled plain, 64″ wide, very level." Will one of our friendly selenographers be good enough to inform me how many craterlets have been discovered on the floor of above?—JASON.

[61645.]—**Lime Light.**—Would some correspondent kindly give me a little information on the following subject? A friend of mine has a good oxy-hydrogen blowpipe, and he wants to fit it up as a lime light. If not asking too much, I should like a drawing of lamp, reflector, position of lime ball, quantity of gas necessary to use per hour to keep the light up, best kind of lime ball, &c.—J. L.

[61646.]—**Winding Rope.**—How can I find out whether a winding rope is made of charcoal iron, Bessemer steel, Siemens-Martin, or crucible steel wire? Also, where can I get a bit of honest charcoal iron wire?—W.

[61647.]—**American Organ.**—Will some one of our musical correspondents answer me the following? I intend making an American organ with one full row of 8ft., one full row of 4ft., three octaves of 16ft. in treble, and two and a half octaves of 8ft. in treble. The 8ft. and 4ft. rows will be in front, and the three and two and a half octaves at the back. There will be also two octaves of large scale for pedals. I want the 16ft. reeds voicing to imitate the violoncello (for solo playing), the lower half of 4ft. for principal, upper half for flute, bourdon for pedal reeds. Now what should the full row of 8ft. and the half row of 8ft. be voiced to, to give best results? It will be F scale, and have octave-coupler up and down. What size should bellows, wind-chest, &c., be? Do not pinch me for wind. Would it answer to have the 8ft. row of a soft quality tone, and make the two and a half octave 8ft. into three octaves of a very reedy character, as I should like an oboe or other reedy stop?—J. S.

[61648.]—**Battery for Lamp.**—What number of cells of following kind would be required to work one of Shippey Bros.' 8-volt (5c.p.) battery lamps? Outer cell, 7 by 5, with three carbons, each 5 by $1\frac{1}{4}$ by $1\frac{1}{4}$; porous cell, 6 by 3, with zinc rod 5 by $\frac{3}{4}$; charged as follows: outer cell, water, 3oz. bichromate potash, 4oz. sulphuric acid; inner cell, 2oz. mercury, $\frac{1}{2}$oz. sulphuric acid, water. In having a lifting arrangement, is it necessary to lift carbons as well as zincs? I want to fix lamp about 10yds. from battery. What should be smallest size (B.W.G.) of conductor, and would that length of wire necessitate any extra battery power? If so, how much?—AMBER.

[61649.]—**Defective Accumulator.**—I have made a 6-cell Planté accumulator, with two plates in each cell, each plate measuring 5 by 17. I soaked the plates first in nitric acid for about 14 hours, and then washed them thoroughly (I noticed they were slightly yellowish when dry). I then rolled them up with strips of thick felt in between, and put in the acid. I charged them in series from a small dynamo, reversing the current about ten times and charging for about a quarter of an hour each time. I only noticed one cell giving off gas. On testing at the end of that time, I found only the least indication of current from the 6in. series. Can anyone explain what is wrong? Also, I have heard that 5 per cent. alcohol in the acid assists the formation. Is this correct? I have taken out the acid, and am now anxiously awaiting a reply.—PLANTE PLATE.

[61650.]—**Micro. Object-Glasses.**—I should feel extremely obliged to Mr. E. M. Nelson if he would kindly advise as to what object-glasses are best suited for the study of the lower organisms, both animal and vegetable, cost being somewhat a consideration. I should at the same time be very glad to know what Mr. Nelson thinks of Zeiss' ordinary objectives, especially the high-power immersion ones—whether they are equal in performance to the corresponding powers of English makers.—J. H. ARTHUR.

[61651.]—**Induction Coil.**—Will one of our able correspondents kindly tell me how to test the continuity of the scondary wire of my coil, containing about $1\frac{1}{4}$ mile of No. 40 s.c. wire? I made it a few years ago. It has been knocked about a good deal, and I don't at present get as long a spark from it as I used to do. I think the secondary has parted somewhere.—J. P. AIGBURTH.

[61652.]—**Screw Cutting.**—Will an experienced hand kindly inform me how to cut an exact Whitworth thread, having $\frac{1}{6}$ rounded off top and bottom, without using a chaser? I have an ordinary V screw-cutting gauge; but when the tool is simply ground to this, I find it difficult to produce accurately-fitting male and female threads.—FOREMAN.

[61653.]—**Colliery Superstitions.**—Can any reader of the ENGLISH MECHANIC give information as to an idea which seems to be somewhat prevalent among colliers, that there is a "straining of everything in the mines" at midnight? As the idea has been given me from two independent sources, an English miner and a Scotch, there would seem to be a pretty widespread superstition on the subject. The account given me was that at midnight the miners assembled at the main shaft to be out of danger in case anything should come down, as if any coal were to fall it would fall at that hour. The explanation given by the miners appears to be that the earth is upside down at the hour of midnight.—GARRISON GUNNER.

[61654.]—**Sidney's "Arcadia."**—Is any cheap edition of this book in existence?—GARRISON GUNNER.

[61655.]—**Finishing Size.**—I have a number of gold flats to gild and finish in the best manner possible, but cannot get a good finishing size. Would someone kindly inform me how this size is made, so that I can make my own? I have tried to find out how to make it by experimenting, but have failed.—W. A. T.

[61656.]—**Amalgamating Copper Wire.**—Would one of your correspondents kindly inform me as to the best way of amalgamating the ends of copper wire?—IOTA.

[61657.]—**Hypopus Vulgaris.**—Can any reader kindly inform me what this animal is? Its calcined shell is used for making phosphorescent sulphide of calcium.—PI.

[61658.]—**Dyeing Canoe Sails.**—Can anyone tell me how to dye the cotton sails of my canoe a light golden brown? Details of materials and quantities will greatly oblige—KYAK.

[61659.]—**Spiral Springs.**—I should be glad if I could obtain, through the medium of your valuable paper, some information as to the mode of manufacture of spiral springs for safety valves, &c., and as to the machinery used in making them.—RESSORT.

[61660.]—**Picking Lever Locks.**—What is the method employed in doing this? The lock to be operated on is a well made six-lever one.—J. W. R.

[61661.]—**To S. Bottone.**—I have made a medical coil according to instructions given by you in the "E. M." (my numbers are at binder's) some short time since, and with a quart bichromate can get small shocks when I rub the negative wire against the binding screw; but experience nothing when the wire is under; neither will the hammer vibrate. The shaft is a steel spring, the head of brass. I don't wish to put on the secondary till I know I am safe, although there is no shock when the wire is under the binding-screw. The core is a temporary magnet. Should my connections from the binders on the base to those on the primary head be platinum wire? Bobbins, $4\frac{1}{2}$in. 3in., $\frac{1}{4}$lb. No. 24 dia., $\frac{1}{2}$lb. 36 silk-covered? Am I right?—SAFE.

[61662.]—**Pump for Compressing Air.**—I wish to make a pump for compressing air for experimental purposes. What would be the best style of piston and packing? With a pump of 3in. bore and 6in. stroke, running at 100 per min., would it get seriously heated in pumping, say, 30c.ft. of air to 30 atmospheres?—CYCLOPS.

[61663.]—**Photo. Enlargement.**—Can any reader conversant with photography inform me how I can construct an inexpensive apparatus, or devise any other simple means by which I can enlarge quarter or half-plate photos. direct from negatives on sensitised paper without the aid of the solar camera (the latter being too expensive for an amateur)? I want them enlarged, so that I can paint and fix them in frames about 15in. by 11in. If such an apparatus can be made, I will feel grateful for dimensions, and diagrams, if possible.—D. J. KEEGAN.

[61664.]—**Partial Silvering.**—I require to deposit an ornamental design on a number (500 to 600) of small copper articles (about size of half-a-crown), the design to be in silver (electro-deposited), the copper ground to show through. I can do the silvering, but I cannot find anything suitable for "stopping off." Something like the following might do: printing the article with a "stopping off" substance, using a rubber stamp which would leave the metal bare where the design is required to be deposited. If so, what kind of "stopping off" substance should I use to print with? I could not use a stencil, as the articles are slightly irregular, and it might smear the design.—BETA.

[61665.]—**Portable Engine.**—Can some reader give me some instructions as to putting firebox in portable engine, 8 horse-power, the best way to get old box out and put new one in?—in fact, all particulars will help me. I am afraid the bottom of boiler is thin. How should it be done? If it must have a piece put round bottom, should the bottom be cut off or the piece put on top? Would it be best inside or outside? How done at corners? What thickness should it be? Would $\frac{1}{4}$ be strong enough, or must it be $\frac{3}{8}$? How near rivets to make a strong and neat job? Can stays be broken off, or must they be drilled out? Can rivets be cut off at bottom, or drilled out?—ENGINEMAN.

[61666.]—**Non-conductor Insoluble in Ether.**—Would any of the readers of the "E. M." kindly assist? I want a substance for lining a metal box of small dimensions, temp. at or below freezing point, to be a good non-conductor, and not acted upon by ether. I thought of thin wood or wood pulp faced with vulcanite, so as to have a total thickness of $\frac{1}{8}$in. Can anyone suggest a better plan?—AMATEUR.

[61667.]—**Tempering Tools.**—I propose to temper tools by making them dead hard and letting down in hot oil. Wanted, a list of the various temperatures required.—DANDIE DINMONT.

[61668.]—**Walnut Veneer.**—How do cabinetmakers "fake" the light and bad places in above? What colours do they use, and how are they applied?—DANDIE DINMONT.

[61669.]—**Sharpening Carpenter's Tools.**—I have often thought that a circular Turkey stone running in a lathe would give better results than the ordinary flat one. Can anyone say if this this has ever been tried, and, if so, how the proper shaped stone is obtained?—DANDIE DINMONT.

[61670.]—**Theory.**—Would some of our Honours men tell me what knowledge of electricity, theoretical and practical, is necessary to pass in Honours stage of electric lighting, City and Guilds Exams.? Could a pure theorist pass first-class by reading up, or must he have some practical experience?—ELECTRICAL STUDENT NO. 2.

[61671.]—**To Mr. Conry, Mr. Bottone, &c.**—I have read a covered wire keeps cooler than an uninsulated one if carrying a heavy current. Is this the case, and, if so, why? In the bottom of the old Clarke gas-lighters there is a cavity for a drying agent. Having tried calcic chloride in vain, I would like to know what substance would suit best. Would one of our electrical friends kindly explain the best and readiest means of calibrating a volt and ampère meter. I have made current from about $\frac{1}{2}$ to 15 ampères, and E.M.F. from 1 to 20 volts?—ATOI.

[61672.]—**Electric Lighting.**—Will Mr. Bottone kindly help me in the following? I want to light twenty 20c.p. lamps, parallel arc, and have a $2\frac{1}{2}$H.P. Otto gas-engine. The distance is not great—say 30 yards. What would be best size of dynamo and cables, and what sized sheaves would be best for engine and dynamo? Would you recommend accumulator for this, as lights would be required, say, during winter, four hours a day, and, if so, what size ought they to be?—JANUARY.

[61673.]—**Dynamo.**—Perhaps some of your obliging correspondents would kindly reply to the following: I want to make a dynamo to light up all the house (I can buy a steam-engine cheap). It will require thirty 20c.p. lamps. I want to know what kind would be best to make and the length and diam. of the F.M., size of armature, size and quantity of wire for armature and F.M., with any additional information the obliging gentleman may think necessary. If F.M.'s are rectangular, the breadth and thickness, as well as length, will be required.—WEE SANDY.

[61674.]—**Butterine.**—Although I am for the present residing in an agricultural district where butter is plentiful, I cannot get butter I can eat. I believe I got more than one sample of butter and pig's fat, mixed when the butter was taken off the churn. I want to know how I can prove this to be so. Could the butter be separated from the pig's fat by one who is not up to chemical analysis, or must it be sent to an analyst?—A. B. C.

[61675.]—**Cardiac Affections.**—Will Dr. Allinson, or any other medical authority, explain the symptoms whereby a person may conclude that regurgitation is present in any valvular derangement of the heart? Can regurgitation exist apart from any dropsical condition of the extremities of the body? What are the chief symptoms which indicate the presence of a slight backward flow of blood, which may result in consequence of defective valves? Do cardiac diseases tend to produce aneurism of either veins or arteries? Any information will be received with gratitude.—G. F.

[61676.]—**Pitch Striker.**—Will some kind reader enlighten me on the pitch striker in "Greenwood's" Handbook, as I wish to make one, and do not properly understand its make and action?—YOUNG TURNER.

[61677.]—**Steel Castings.**—Would any of your readers kindly give me particulars of any substance used in the moulding of steel castings to facilitate dressing or fettling the castings?—G. W. T.

[61678.]—**Violin Bow.**—I have made a bow, but want to curve it a little more near the top. How can it be done best? I am told it is done by dry heat. Is that so?—BRUNO.

[61679.]—**Photographs.**—TO R. A. R. BENNETT.—Thanks for your information. I believe I have a real positive, as when held up to the light, light and shade appear in their proper places, as in a print you tell me to take a negative from it "by contact." Would you kindly explain how this is done?—DUSTY MILLION.

[61680.]—**Pendulum.**—Will some one of our readers tell me how many degrees a pendulum, whose length is 23in. and weight 5lb., should swing on each side of zero according to the scale fixed under the bob? I wish to know in order to regulate an electric pendulum which is hung on a knife-edge, and is quite independent of any escapement. A pendulum 36in. long in a regulator seems to swing about 11 deg. on each side of zero. Should a shorter one do the same?—CHRONOS.

[61681.]—**Electrical Measurement.**—What is the direct difference between a "coulomb" and an "ampère," and is the old electrical unit termed, a "veber" exactly equivalent to a "coulomb," or to an "ampère"?—BETTLER.

[61682.]—**Colombmetre.**—What is the exact purpose served by a colombmetre—its construction and usual price?—INVICTA.

[61683.]—**Organ Music.**—Would Mr. Audsley kindly indicate a few pieces of good chamber music with easy pedalling for a novice with classical leanings?—INVICTA.

[61684.]—**Harmonium.**—I shall feel obliged to G. Fryer if he will explain how to make a voix celeste stop without putting the reeds out of tune, as I wish to add that stop to my instrument.—H. E. S.

[61685.]—**Spring of Beam.**—A beam is firmly bedded in two walls for its support. Length of beam, 20ft. A weight of ten tons is placed in the centre of the beam. What springing force will it bring on the walls?—E. T. GEE.

[61686.]—**Tin-plate Creaser.**—Will anyone kindly inform me how to make a small machine for making a crease and smoothing the edge of the tin after the wire has been put in, which will gauge to certain thicknesses and width by means of a screw?—A READER.

[61687.]—**Water Pressure in Towns.**—Will some reader kindly inform me (in a few instances) where water from a high level reservoir works a set of pumps or other contrivance to force water to a higher district?—J. G.

[61688.]—**Condenser.**—Can any reader tell me what size and gauge copper a condenser should be to put outside a small launch? Engines, 3¾in. by 5in., high pressure. Also, how is it connected, and where does the pump draw from?—A. L.

[61689.]—**Dynamo.**—Could any reader inform me whether the coils of a dynamo are liable to fuse when they get hot, as I find they do when all the lights are on? The dynamo in question supplies a mill with about 130 16c.p. lamps. I should also be glad to know long a dynamo ought to last, being in use day and night.—ZANONI.

[61690.]—**To Mr. S. Bottone.**—I have a shocking coil. It is wound with ½lb. of 18 cotton-covered wire for primary and ¾lb. of 32 cotton-covered wire for secondary. It is very weak. Is there any way of improving it, say by rewinding and insulating with paraffin wax?—A. FOX.

[61691.]—**Engine.**—To "T. C., BRISTOL."—I have a cylinder, 5in. stroke, 3in. bore. What weight and size of flywheel should I want for above, and what H.P. would it be? The port-holes in cylinder are ⅜ round. Are they large enough?—YOUNG BEGINNER.

[61692.]—**Electric Lighting.**—Will any of "ours" kindly help me in the following? A and B are two dynamos; C and D two incandescent lamp circuits. It is required to have switches arranged in such a way that machine A can be switched on to circuit C or D, and also the same with B machine; but that no two machines can be on the same circuit at the same time. The ordinary arrangement would be A on C circuit, and B on D circuit; but in case of emergency, I wish to adopt the above. Kindly describe kinds of switches and arrangement to be used.—ELECTRON.

[61693.]—**Water.**—What quantity of water per week is required for two boilers, engine running 62 hours? Cornish boiler, 13ft. 6in. long, 5ft. diam.; inside shell, 13ft. 6in. by 2ft. 9in.; steam chest, 3ft. 3in. by 3ft. 3in. (inside measurements); firegrate, 3ft. 6in. long by 2ft. 8in. wide; height from firebars to inside shell, 1ft. 3in.; vertical boiler, 9ft. 9in. by 5ft. 6in. (inside measurement), two cross tubes, 7in. diam.; height from firebars to crown of inside shell, 5ft.; firegrate, 4ft. 6in., connected together by 3in. pipe, and work a 16 horse-power engine; fires banked at night; 1½in. pipe from said boilers to two steam boiling pans, and heating three hot rooms.—S. S.

[61694.]—**Lucigen Light.**—I should like to see the lucigen light described in "Ours." I believe it is now being used at the works of the new Tower Bridge. Will someone oblige?—H. F.

[61695.]—**Aromatic Burning Ribbon of "Bruges."**—Can anyone say how this is prepared, especially the method of obviating the pungent odour generally attendant on the destructive distillation of cotton or flax? Is it partially guncottonised before the aromatic gum and saltpetre is put on, and if so, by what strength of acid, and for how long?—PHOS.

[61696.]—**Oil Stains in Photographs.**—What is the best way to remove oil stains from photographs?—COOPER'S HILL.

[61697.]—**Violin.**—Will some one tell me how to fill a bow with hair, and also how it is that in some violins the belly near the bridge is much darker than the rest of the violin, and how it is produced?—A. W. F.

[61698.]—**Laundry Blue.**—Can some one say what are the different constituents of the various blues known under the above name? Is anything besides indigo and ultramarine used, and if so, what, how, and by what makers?—PHOS.

[61699.]—**Electro-Plating.**—Will some one please tell me if for electro-plating I connect the vats in series, shall I be likely to obtain better results by having anodes each side of cathode? Also, what copper wire is best to use from the dynamo to brass rods, as the ordinary corrodes so quickly? Any hints as to better mode of placing rods will be acceptable. Also how can I best connect up for small gilding and still have the other baths working, the gilding to be done without suspension rods in the old way?—ELECTRO.

[61700.]—**Nickel Crucibles.**—Are these (see p. 497) to be bought? From what is said, they would be useful. Will they stand fusion of silica to make water-glass? If so, they will save my platinum.—R. S. T.

Progress of Electrical Industries. — A notable instance of the development of electrical industries within recent years is seen in the works of Messrs. King, Mendham, and Co., of Bristol. Year by year the firm have found it necessary to enlarge their premises in Narrow Wine-street and Fairfax-street; but lately they have been compelled to seek additional quarters in another part of the city, Denmark-street, where they have an extensive display of electric and optical apparatus in great variety.

THE annual value of the mineral products of the United States is about 425,000,000 dols., and some 800,000,000 dols. are invested in the mining industry. Mining furnishes employment to 500,000 men. In Montana alone, the newest mining country, 50,000 people are dependent on silver and gold mining. Leadville has produced 114,000,000 dols., and is good for many times that amount. The production of California alone in the aggregate runs far beyond a billion of dollars. Nevada has yielded her hundreds of millions, and all the other States and territories have produced their quota of riches.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Feb. 9, and unacknowledged elsewhere:—

A. S. JONES.—S. Ford.—E. E. Hibling.—Cooper Cooper and Co.—J. B. Blew.—J. Harrison.—Sir O. H. P. Scourfield.—G. H. V.—W. H. Kope.—T. E. F.—Glatton.—S.—Bagot.—Volt.—J. M. G. and S.—Slandingo.—Acier.—T. F. S.—G. and S.W. Ry. Fitter.—H. B. Edwards.—J. Fletcher.—H. Watson.—W. R. W.—H. D. B.

ANXIOUS. (No, unless the substance is itself a magnet. Adamant is a name applied to the diamond and also to the loadstone—"You draw me, you hard-hearted adamant, but yet you draw not iron; for my heart is true as steel."—"Midsummer Night's Dream," ii. 2—hence the origin of the statement about adamant and the magnet.)—SLUGGARD. (See No. 725, p. 564, for a simple arrangement for an electric-clock alarum. There are many others in back volumes; but it is really very easy. Procure a clock in which the frame is of metal; fix an insulated contact piece at the hour at which the alarum is desired, and attach metallically a little wire brush to the short hand of the clock. The frame of the clock is then connected to one pole of the battery and the insulated contact piece to the other. When the brush sweeps over the contact piece, the bell, which is in the circuit in some convenient position, will ring as long as the contact lasts. By putting the clock fast or slow, the bell rings at any desired time.)—AMETURE, NO. 1. (Molasses, treacle, syrup, tar, pitch, or any other carbonaceous matter; but it will be necessary to burn them, and when the job is completed they will not be so satisfactory as sound plates. Other methods have been described in back numbers. It is better to break them up and use them in other batteries.)—NOVICE. (The numbers are out of print; but no doubt you could obtain them by inserting an advertisement in the "Wanted" column.)—AMPERE. (If by "electrician" you mean electrical engineer, the only way is by apprenticeship. As you have "studied electricity for a long time," probably you would not find much difficulty in obtaining employment.)—A. ADAMS. (See indices. You do not say whether the clock has a bell or not. 2. Bronzing copper urns has been frequently described. Several methods are given in No. 593, p. 527; but it is special work requiring much practice.)—J. C. C. (What is meant by a "cheap method"? If you cannot refer to back volumes, see Watt's "Electro-Metallurgy.")—HECTOR. (Soak the spot with benzoline, cover with blotting-paper and pass a warm flat iron over, or cover with Fuller's earth and place a warm iron on it.)—ANGULUS. (For a good method of treating incipient baldness, see p. 456, No. 1061, and many recipes in back numbers. You should endeavour to discover the cause.)—H. D. T. (No age mentioned, so it is impossible to say whether your eyesight will improve as you grow older. The probability is that the myopia will remain with you.)—GREENHOUSE. (Ordinary putty is as good as anything; but it is as well to apply paint at the time it is put on. The only radical remedy is to abolish putty or anything like it, and use one of the patented systems of glazing. They are widely used because putty is unsatisfactory here, and we presume it is at least equally so in Darjeeling.)—LIVRE. (Reynolds's "Elementary Chemistry" is published by Longmans in three parts, price 1s. 6d., 2s. 6d., and 3s. 6d. 2. Heather's "Plane Geometry," Crosby Lockwood and Co., 2s.; but see publishers' lists. 3. Depends on what you want. Warren's "Elements of Machine Construction and Drawing," published by E. and F. N. Spon at a guinea and a half, is a good work; but perhaps Unwin's "Elements of Machine Design," Longmans, 8s. 6d., or Maxton's "Manual of Engineering Drawing," Crosby Lockwood and Co., 3s. 6d., would suit.)—S. C. (Laboratory work is absolutely necessary; but see pp. 421, 443, 465, 486, last volume.)—WANTS TO KNOW. (Tallow is a commercial article, and can be bought in the usual way. Do you want to know how to melt fat down into tallow, or what?)—J. L. (Pitch, or cement, or plaster of Paris; but it would be advisable to have the job done properly, even if it does cost as much as a new gutter.)—COMBUSTION, Newcastle. (Such a query should go into the "Addresses" column. If still in existence, no doubt Melhuish and Son, Fetter-lane, keep them.)—A CONSTANT READER. (If executrix is to have interest during her life, it is not easy to see how the principal can be divided. It depends on the terms of the will.)—DRAUGHTSMAN. (You must endeavour to discover the cause. If a medical man cannot, after personal inspection, it is scarcely likely that our correspondents could guess it. Try a change of diet.)—OILS. (Mount your pictures with strong flour paste containing alum.)—DRYPLATE. (See indices. Most users buy them, as they cannot be made cheaply in small quantities.)—STATUE. (To remove rust from marble, see p. 197, No. 1076. To clean from stains, see p. 562, No. 1117, and the indices of back volumes.)—PANDO. (You must say whether you mean lacquer or what. Perhaps it is collodion, and perhaps again glycerine.)—Q. E. (F.S.A. mean Fellow of the Society of Antiquaries.)—R. M. (There is no method of absolutely melting horn and running it into moulds; but it can be softened by immersion in hot water, and then can be pressed into shapes by means of powerful moulding presses. The shaped pieces are joined together by carefully heating the edges over a clear fire, taking care not to handle or grease the surfaces to be joined.)—STEEL. (Perhaps it is rouge, coloured whiting, red ochre, or a dozen other things. You should have a sample analysed.)—GLOVASKI. (A full description, with illustrations of Noble's comb, is given in McLaren's "Spinning Woollen and Worsted" (Cassell). The principle consists in dabbing a lock of wool on two sets of pins placed close together, which are afterwards parted so that a portion of the wool adheres to each. The noil is left behind and is lifted out by knives set between the pins.)—UNEMPLOYED. (Do you mean reflector or refractor, or does the query relate to size? A good 3in. telescope mounted on a firm tripod stand, would do well for street exhibition purposes.)—DUMB. (Only the very finest emery should be used to clean brass. If it is worked brass, clean with a solution of oxalic acid, and polish with whiting and a brush or soft leather. Elbow grease is the principal factor in brass polishing.)—G. TELA. (You will probably find what you want at David Nutt's, in the Strand, or at Williams and Norgate's, in Henrietta-street. At all events, they would be able to tell you whether there are such works as you require. There are good dictionaries of technical terms in German; but it is doubtful whether any general dictionary includes all the words used in scientific books.)—FITTER. (See the "Notes on Plumbing," which appeared in Vols. XXXIV. to XL., and procure the manual issued by Mr. Eldridge, 54, Murray-street, Hoxton, N.)—LADY GARDENER. (That is really a rather large bed. Smaller ones are preferred. As to quantity, put in pieces of the brick about the size of a walnut at every 3in. or so. If the bed is at proper temperature, and the spawn good, the latter will find its way all over it. 2. It cannot be altogether avoided; but much may be done by thorough kneading and having the oven at the proper heat before putting in the bread.)—COLOUR. (There are several preparations of the kind; but we do not remember the addresses. As a rule, they are sent to architects and builders, and probably you would find the material to which you refer advertised in the *Building News*.)—FRUSTRATED. (Rub well with a damp cloth, and restore colour if necessary with an aniline dye. Then rub over with glair—that is white of eggs beaten to a froth, and allowed to fall into a clear liquid.)—J. C. C. (You should always mention the page on which the matter referred to appeared. No. 1010 is in print, and can be had from the publisher for five halfpenny stamps; but you should state what it is you wish to plate, and whether you have battery or dynamo.)—H. K. F. (Which new hot-air engine? We have given illustrations of nearly all, at one time or another. Do you mean the engine illustrated in No. 1099, p. 148, or those which appeared in Nos. 1078, 1084, 1088?)—F. J. B. (If you mean on the construction of the violin, procure Davidson's book from Pitman, Paternoster-row, E.C.; if on the art of playing, obtain Spohr's work from Augener and Co., Newgate-street, E.C.)—COOPER'S HILL. (Only by hunting up the various papers and magazines, or by direct application to the secretaries of the respective companies. 2. We believe a blue-book has been issued, or is about to be, on the subject. 3. No, except that it avoids the fumes.)—F. W. W. (The question has been answered many times. If the present gas-burners are sufficient, you will want the equivalent in incandescent lamps; but the circumstances might render it advisable to have lamps of greater power, and fewer of them. A two-man power gas-engine is, however, too small to do much in the way of electric lighting. See recent replies—one on p. 505, for instance.)—DENTIST. (Read previous answer. To obtain steadiness, as heavy a flywheel as possible is required, and the engine should always have more power than is actually required. A one-man gas-engine would only do for experimental purposes.)—ELECTRO. (The methods of polishing and burnishing silver and other goods have been frequently described; but if you cannot refer to back numbers you will find details in Sprague's "Electricity," or in Watt's "Electro-Deposition." Other question inserted.)—J. (Probably the magnets want remagnetising. How is the line erected?)—R. J. T. (You do not say, but presumably the gold solutions are for plating; but then you do not state how they are made up, nor how used, and answers could be little more than guesses. State the composition of the solution, how long it has been worked, whether the supply of gold has been kept up, and other particulars.)—PRINTER. (Hill and Co., 46, Essex-street, Strand, W.C., will quote prices for either wood or zinc blocks suitable for printing from. 2. The other question has been recently answered. You can purchase old type-metal, or prepare stereo metal by melting together four parts of lead and one part of antimony. See answer to "Stereo" last week, p. 510.)—W. B. H. (No book that is to be relied upon; but many hints, &c., in back volumes. It is advisable to purchase a pan, and it would be cheaper than the American organ of the same size, as the latter requires voiced reeds. The best plan is to hire instruments for a short time.)—COMET. (This query, without a signature, asks rather too much, as it would involve a long search in the library of the Royal Astronomical Society, or a similar institution, and the information, when found, would be of interest to few (if any) besides the querist.)—TCHIPS. (It is easily done without the preliminary motions of raising the hands five times slowly above the head, if the four operators will inhale deep breaths in time with one another, and hold the breath. The man lifted should also inhale and retain his breath; then it is said it can be done with the fingers alone; but even in your case the weight each man lifted was less than 56lb. In the first case—that is, without the preparation—the combined efforts were not made simultaneously.)—OLD FIREWORKS. (Simply a little fulminate of mercury put between two strips of glass-paper, which are separated in opposite directions when the "cracker" is pulled.)

The English Mechanic
AND WORLD OF SCIENCE AND ART.
FRIDAY, FEBRUARY 18, 1887.

NOTES ON NEBULÆ.—V.

G. C. 600 = M 77 = *h* 262. A.R. = 2h. 35m. Dec. S. 0° 35′. A very bright nebula, diam. about 1′, brightening rather quickly to the middle, where there is an almost star-like nucleus with 150. With 320 less stellar; but the object being low, the definite was not good. The proximity of a star 10 mag., at 2′ *s.f.*, makes a striking object, the nebula being nearly of the same brightness. The star and nebula both give a continuous spectrum with a direct-vision prism. The nucleus seemed to sparkle at times (moonlight), Nov. 17, 1886.

G.C. 544 = H IV. 23 = 223*h*. A.R. = 2h. 20m. Dec. S. 1° 46′. Large and faint at edges, gradually brightening to a condensed patch in centre (perhaps a little *p.* the centre of nebulosity). Only star near is a very faint one, 13 mag., about 3′ *p.*, a little N. (D'Arrest says, "* 14 mag., prec. 12·4s., 70″ *ad boream*), extent of nebulosity about 2′ (moon rising and sky luminous). Power, 150. Nov. 17, 1886.

Apparently resolvable with 150, Nov. 18, 1886.

G.C. 434 = D'Arrest 31. A.R. 1h. 47m. Dec. N., 20° 1′ (near β Arietis). Exceedingly faint, a very small star 13 mag. preceding. This is a most difficult object without the air is *very* clear, as the illumination round the bright star β Arietis 7′ dist. quite masks it. Nov. 18, 1886; power, 150. Exceedingly difficult and faint, only seen as a suspicion, and yet one is almost certain it is there, just *s.f.* a 13 mag. star. Nov. 21, 1886; 150.

G.C. 2360 = H I. 170 = *h* 847. A.R. = 11h. 10m. Dec. N. 59° 33′. A rather bright nucleus (looking at times multiple), surrounded by haze rapidly fading away. About 2′ diameter outside; but object rather low down in hazy sky. Power, 80. With 200, nucleus appeared elongated in meridian; an exceedingly faint star following almost in the coma. Apparently resolvable.

G.C. 2362 = H I. 271 = *h* 848. A.R. 11h. 10m. Dec. N. 58° 45′. Very pale, rather large and diffused, not much condensed (but sky not clear). A small 12 mag. star prec. at 5′ ±. With 200, and clearer sky, much brighter towards centre, and nucleus granulous, looking like an irresolvable cluster. Nov. 21, 1886.

G.C. 2620 H IV. 62 = *h* 1017. A.R. = 11h. 48m. Dec. N. 55° 54′. A curious object, like a faint, double star in a bright haze fading gradually away. Diameter about 2′. Powers, 100 and 200. Nov. 29, 1886.

D'Arrest does not mention the nucleus as being double. He says: "Rotunda, clara, versus meditullium gradatim lucidior; Diametrus = 45″." 1866, Oct. 7. Also on Oct. 16, 1866: "Adspectu omnino cometari; clara, rotunda; diam. = 50″."

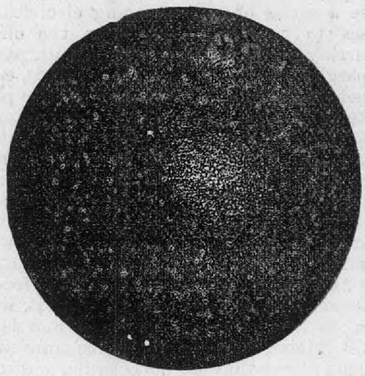
G. C. 2606 H V. 45 = *h* 1011 A.R. 11h. 46m. Dec. N. = 53° 6′. Very cometary, large and diffused, moderately bright, extended N. and S. Brighter to middle, which appeared to consist of several faint stars, almost resolvable — diameter about 3′; 11 mag. star following at 2′ ±; powers 100 and 200. Nov. 29, 1886.

D'Arrest says: "Circa centrum perlucida; grandiuscula propemodum rotunda. Prævia fixa 15 magn.; nebulositate illegate, inter stellulam et neb. centrum 38″ exquisitissime."

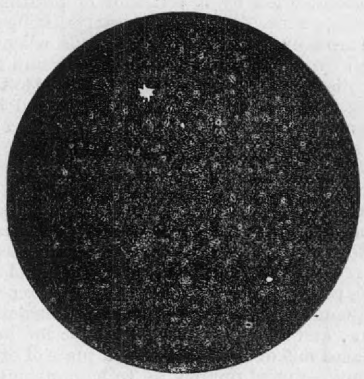
G. C. 1225. H IV. 34 = *h* 365. A.R. = 5h. 34m. Dec. N. 9° 0′. Planetary, small and rather bright, slightly oval, at times looking as if it had a double nucleus 12 mag., but light rather evenly distributed; powers 100 and 200. Nov. 29, 1886.*

G. C. 2413. H I. 194 = *h* 887. A.R. = 11h. 18m. Dec. N. 44° 22′. Large and diluted with low powers—about 2′ diam.; but faint nebulosity extended in a slightly lenticular form, *s.f.* and *n.p.* With higher powers (200), the brighter central part looks like a mass of very small stars unequal in size, giving to the whole a mottled aspect. A very faint double star, 14 mag., precedes at about 3′; and another 14—15 mag. star lies at about 2′ S., almost involved in the nebulosity. D'Arrest does not mention these stars. Dec. 24, 1886. (Sky not very clear.)

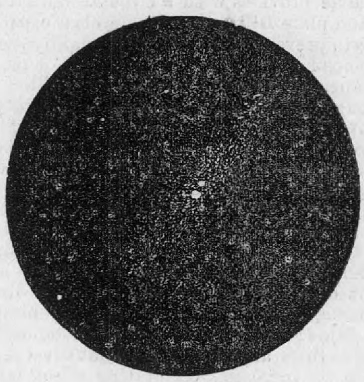
G. C. 2404. H I. 219 = *h* 881. (A.R.



G C 2413



G C 839
(T TAURI)



G C 2668

11h. 17m. Dec. N. 39° 32′.) Pale, rather faint, gradually brighter towards the middle, but no nucleus, apparently resolvable, but not so strikingly so as 2413; and with 200 not so mottled as with 100—about 1′ diam. A 13 mag. star follows at about 2′. Dec. 24, 1886.

G. C. 2227. H I 362 = *h* 773. (A.R. = 10h. 43m. Dec. N. 28° 43′.) This is rather a conspicuous nebula, and although placed by H in his second class, is brighter than 2404; a very faint 14 mag. star a little distance (2′ ±) S. The nebula brightens quickly, and a sharp, bright nucleus = 12 mag. star, almost stellar. Powers 100 and 200. Dec. 24, 1886. (The 14 mag. star is not mentioned by D'Arrest.)

G.C. 2723. H I. 195 = *h* 1088. (A.R. 11h. 59m. Dec. N. 45° 51′.) A curious object, with low powers very bright, but rather small—about 1′ diam.; but with 200 it apears to brighten suddenly to a bright oval nucleus about 8″ × 12″ elongated *s.f.* and *n.p.* The coma surrounding is also drawn out in faint wings in same direction to extent of about 2′. Dec. 24, 1886.

G. C. 2836. H I. 89 = *h* 1171 (A.R. 12h. 11m. Dec. N. 28° 58′. Bright, not very large, about 1′ diam., brightening suddenly to a nucleus which appears elongated and double at times at an angle of 20° ±. The nebulosity appears more on the south side of the nucleus. No star near. Powers 100 and 200. Dec. 24, 1886.

G. C. 2855. H I. 75 = *h* 1186 (A.R. 12h. 13m. Dec. N. 30° 4′). Large, about 2′ diam. Pretty bright and not very condensed, gradually brighter towards the centre, but no nucleus. Power 100. Dec. 24, 1886.

G. C. 2851. H I. 75 = *h* 1185. (A.R. 12h. 12m. Dec. N. 30° 24′). Very pale, large and cometary, very diffused. Elongated on the parallel, about 1′ × 2′. No nucleus, only gradually a little brigher towards the middle. A 13 mag. star about 2′ S., and an excessively faint star in the coma preceding the centre. It is described in the G. Cat. as much brighter to a nucleus, and D'Arrest's observation on May 12, 1864, says: "In centro æquat. fixam 11 mag."

This is worthy of note. The sky was not very clear when the above observation of my own was made; but I could not have missed the 11th mag. star if in centre.* Power 100. At times I seemed to glimpse a very faint nebula just *s.f.* this and nearly between it and 90 H I. Dec. 24, 1886.

G. C. 839 = Auw. N. 20 (A.R. = 4h. 13m. + 9° 12′ Dec.) Hind's variable (?) neb. near T Tauri. Dec. 29, 1886, searched for the nebula. The variable star was about 12 mag. Could not distinctly trace any nebula near it, but saw O. Struve's and D'Arrest's faint nebula prec. it by about 12 seconds. Very faint and difficult, about 40″ diam., but only seen by glimpses with power 200. (The night not very clear, and much trouble with dew on o.g. Air mild, but ground covered with snow.)

January 26, 1887. Again searched for Hind's nebula. I could see no nebula round or near the variable T, which appeared about 12-13 mag., brighter than the faint star, about 60″ north of the 10 mag. star, a short distance *s.p.* I certainly glimpsed D'Arrest's nebula seen on Dec. 29, 1886, as above stated. This with 200. With 320 there seemed to be a number of very small stars glimpsed between the variable and the bright 10 mag. star. However, I carefully examined T, and it was certainly free from any nebulosity.

C. G. 880 = *h* 322. A.R. = 4h. 30m. Dec. S. 3° 35′. Very faint and difficult. A very faint star just north, only seen by glimpses. D'Arrest says: "Debilissima quidem, sed manifesta et indubia." ν Eridani precedes the nebula by 48 sec. The nebula is easier seen with 700 than 100. Jan. 26, 1887.

Very faint and seen by glimpses. Jan. 28, 1887.

G. C. 200. 2668 = H I. 253 = *h* 1050 (A.R. 11h. 54m. Dec. N. 62° 40′).—Pretty bright, elongated in the parallel, gradually brighter to the middle; but the ends lengthened out into a faint ray or wisp on either side, but more so on the following end. The nucleus appears to be a faint double star (sometimes there appear to be more than two points; but apparently arranged in the parallel = 12 mag.) There appears to be an excessively faint star in the nebulosity just N. of the nucleus, and a 13 mag. star a short distance *s.p.* Also one at some distance S. with suspicion of several other faint points in the neighbourhood. Extent of nebulosity

* Secchi's drawing shows a *dark* centre.

* Or nucleus equal thereto, which Dunér seems to infer.

about 2½' long by 30"—40" broad. Examined with powers 100, 200, and 320. Night clear, but definition bad, and much trouble with dew on object glass, Jan. 28, 1887.

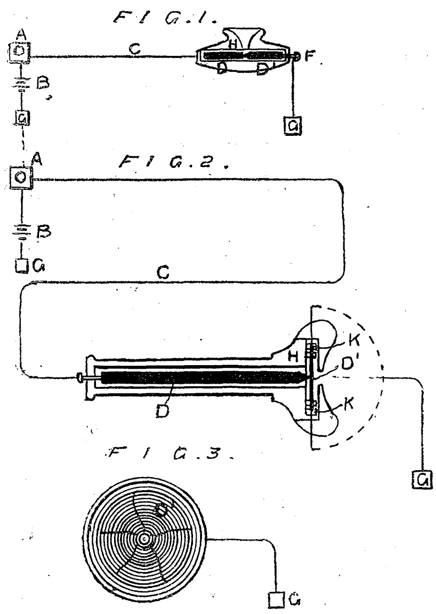
There is a great discrepancy between the description of this object by the two Herschels. H says, "Very bright, very large, elongated," and *h* "pretty bright, 25"; round." D'Arrest's description agrees fairly with my own. It must have been seen by *h* on a bad and hazy night, so that he has missed the faint outlying nebulosity. In the notes to the G. C., Sir John seems to think that the difference in the descriptions are extraordinary, and so I thought till I saw the object, the character of which will quite be altered on a clear or hazy night.

Herbert Ingall.

THE KROTOPHONE.

WE have already at p. 22 ante given a brief account of the Krotophone, an apparatus for reproducing articulate sounds, and now give details with illustrations of the apparatus as patented by the inventor, Mr. E. S. Spaulding, of New York, in this country. The novelty of the invention lies in the method of reproducing the human voice through the medium of crepitations, or minute crackling sounds or detonations, and it particularly consists in causing the original disturbances in the transmitter to be transmitted over the line so as to affect the receiver and cause it to give forth a series of crepitations or intermediate detonating sounds which will have the same articulate value as the original sounds, whereby the human voice will be transmitted electrically from one point to another without the use of magnets, diaphragms, helices, secondary currents or induction coils, or any vibrating or sonorous material whatever in the circuit, thus dispensing with the complicated parts, and the various objections to which transmitters and receivers are liable and subject.

Fig. 1 is a plan of the apparatus employed to



carry out this method of transmitting sound. Fig. 2 is a similar view showing a modification of the form of a receiver, and Fig. 3 represents the circumferential connection of one of the carbon contact points. A is an ordinary transmitter, B the battery, C the line, and G G the grounds or earth plates. H illustrates the simplest form of the receiver or Krotophone in which D D¹ are the carbon points which form part of the circuit or line C, one of the points, D, being rigidly secured in the receiver H, and the other point, D¹, being secured therein adjustably with reference to the other point by means of the screws F. The receiver H containing the carbon pencil points D D¹, and adjusting screw F constitute the complete receiver.

The transmitter A may be in one of the various forms of "microphones," or, in fact, any instrument may be used in which the sound or voice produces a series of crepitations in the circuit, which being transmitted over the line are reproduced in their identical quality between the carbon points in the receiver, which reproduction will have the same relation to the original sound as the original sound or voice had to the crepitations in the first instance.

For the sake of illustration, assume that the circuit consists of a battery, line, and the receiver shown in Fig. 1 to be used as a transmitter and as a receiver proper. Assuming that the current passes through the carbon pencils in parallel lines, any disturbance of the point of contact of these pencils in the transmitter will produce a series of crepitations, which cause a series of corresponding electrical impulses to be transmitted over the circuit. Referring to the receiver, this circuit, passing in parallel lines through the pencil D, causes its points of contact with the opposite pencil D¹ to vary by reason of the elongation and contraction of said pencil D, due, for want of a better term, to the polarisation of the molecules or atoms of the pencil. Now assuming that through the pencil the current passes in a series of many parallel lines, then the movement of the atoms in each of these lines would be uniformly similar and in parallel lines, and thus the disturbances created in the receiver correspond to the impulses affecting it, which impulses in turn correspond with and depend on the primal disturbances in the transmitter. It being shown that the polarisation or disturbance of the atoms in the pencil D in the receiver is produced, it has been noticed that this result is accompanied by a series of crepitations or crackling sounds, which are clearly distinguishable from even the faintest sounds when produced by vibrations or other cause, and from this distinction the patentee infers that the crepitations are strictly "neutral," and he so denominates them. Therefore, as such crepitations are individually neutral, when they are arranged in constantly varying groups, corresponding exactly to the primal disturbances which cause them, if articulate sounds be the primal cause of the disturbances in the transmitter, articulate sounds will be the effect in the receiver. Mr. Spaulding has found that when two pencils of carbon are used as a receiver, the sounds will be audible and distinct, but faint; and to overcome this objection he has replaced one of the pencils by a plate of carbon of such size and quality as to be non-sonorous and non-vibratory, as shown in Fig. 2. This plate he provides with a circumferential ring, K, and plate D¹ has a suitable elastic packing ring to prevent fractures when rigidly secured in place in holder H. In this form of receiver the current passing as before in parallel lines through the pencil D and thence to the plate D¹ over the point of contact of the pencil, the current then radially diverges in every direction towards the metallic ring and thence to the ground as before. This construction gives an amplified sound, and this result is attributed to the radial or diverging path the current takes. In the first form of receiver described, the current passes in parallel lines and the movement of the atoms on each of these lines is uniform, and, consequently, the crepitations are faint; but in the second instance these several lines are not parallel, but diverge, and hence an increased crepitating effect is produced.

The patentee does not claim the transmitter, as the whole invention consists in the method of reproducing the voice through the medium of the receiving device, and from this it is clear that any form of carbon transmitter may be used in connection with the receiver.

So far as Mr. Spaulding is aware, prior inventors have employed some means substantially different from his; for example, in the well-known experiments of Prof. Hughes, the microphone requires a free pencil, and the effect seems to depend on the vibratory effort of the voice or other disturbing cause on the pencil, causing it to move bodily and vary the amount or number of contact points, while those of Bulmer show and claim a diaphragm, and Cook employs a vibrating metallic diaphragm, all of which Mr. Spaulding distinctly disclaims.

A NEW DRAUGHT EXCLUDER.

A NEW draught excluder for doors and windows has just been patented by Mr. T. J. Porter, of Fleetwood, which is certainly novel in its character, and has the decided advantage of being a permanent as well as a perfect preventer of draughts. If we may judge from the excellent testimonials of several well-known architects before us, and the local success which this draught preventer has so far met with, it is the best thing of its kind which has yet been introduced, and bids fair to find a very general adoption, not only as a remedy for existing leaky doors, but in making perfect and draught-proof doors and windows in new houses as they are erected, for which purpose it is peculiarly adapted, giving a neat and cosy finish round the doors, and being most suitable to be glued to door casings before they are painted. This excluder is styled the "Matrix" from the fact that it forms, when fixed, a solid and permanent cloth-lined bed round door casings, on which the doors rest when closed, and the exact counterpart of that portion of the door against which it comes in contact, allowing the door to close and latch solidly, tightly, and firmly without any pressure on spring, and forming a perfect draught and dust proof joint. The excluder consists of a composition in a long narrow strip of warm-coloured cloth, which, when shaped, forms a round bead about ⅜in. diameter, with a flat lip about ⅜in. wide extending from it along its whole length. The excluder is made in 7ft. lengths, each being rolled into a coil. In fixing, a coil is dipped slightly into hot water, which immediately softens the composition, and the lip is then glued or tacked on to the door casing, the bead part being allowed to touch the door when closed. Where the excluder has been firmly attached to the casing, the bead is pressed with the finger firmly against the door and into the corner formed by the door and casing. Being pressed thus along its whole length from top to bottom of the door, a long, narrow, and perfect matrix, counterpart, or shape, about ¼in. wide., of the door is formed, fitting all unevennesses and making a permanent and perfect bed for the door, and a tight joint, effectually preventing the passage of draught or dust. After fixing, the excluder should be left untouched for a few hours, to permit of its setting, and in a day or so it will be quite hard, and form a solid part of the now perfectly-fitting door casing. The excluder is fitted to windows in the same way as to doors, and should it be damaged at any time by a blow the injury can be repaired in a few minutes without unfixing, by softening the part with hot water, and re-moulding it by pressing against the door, as in the first instance.

CELLULOID.

THE recommendation of a committee of the Franklin Institute that an Elliot Cresson gold medal should be awarded to the Celluloid Manufacturing Company will draw renewed attention to a material which, in the words of the committee, is of great possible value, and has been successfully utilised in many important industries. Celluloid has been known and utilised under a variety of names for many years; but as celluloid *per se* it dates from the patent issued to Hyatt Brothers in 1870. The material in its earliest form was first prepared in England by Alexander Parkes about 1855, and from him received the name Parkesine, a subsequent modification being known as xylonite, a material which has been made and sold for years by a company located in Homerton. Parkes prepared nitro-cellulose, or pyroxiline, by treating a pure cellulose with nitric and sulphuric acids, and then dissolving in some such liquid as naphtha (of both kinds), nitro-benzol, or glacial acetic acid. The pyroxiline was then precipitated as a curdy mass, which was moulded and dried. Later he adopted the use of an alcoholic solution of camphor as the solvent, and since then we believe camphor has always been used in the preparation; but the Hyatt Brothers, after considerable experimenting, discovered that melted camphor was a perfect solvent for pyroxiline, and enabled masses to be produced which were thoroughly homogeneous and plastic—all of which will be found set forth in detail in our

earlier volumes. In 1874 the American patent was re-issued, and the manufacture of celluloid in the improved form has been carried on by the company above-named at Newark, New Jersey. At the late "Novelties" Exhibition of the Franklin Institute, the fine display made by the Celluloid Company induced the judges to award them a silver medal, and to call the attention of the Institute to the "introduction of a new raw material of great possible value," which has resulted as mentioned above. In the modern process of manufacturing celluloid a pure form of cellulose is the raw material, and this is preferably a tissue paper specially prepared in large rolls. After "nitration," a thorough washing, and partial drying, it is mixed with a certain proportion of camphor, and the mixture is ground in suitable machines, moistened with alcohol to make it "pasty," and to allow it to be worked at a comparatively low temperature, and is then submitted to a heavy hydraulic pressure for some time. If a colouring pigment is desired, it is usually introduced before pressing the mixture into blocks. The blocks so obtained are broken up, and known as "stock," which is fed between heated rolls and turned out as finished celluloid in sheets, which may be made transparent, translucent, dead white, or coloured with a variety of pigments either in self-tints or stratified and veined in imitation of natural products. Amongst the earliest applications of celluloid was its use as a substitute for ivory in all the manifold purposes to which this beautiful material is employed in the manufacturing industries; and notable amongst them are the keyboards of musical instruments, such as pianos, organs, and harmoniums, handles of pocket-knives and cutlery, combs, brush-backs, and mirror-frames. For the manufacture of billiard-balls it is said to be preferred to ivory, as the spheres can be made of absolutely uniform density throughout, while they can be coloured or made dead white. Celluloid has the advantage over ivory that it does not crack or "craze," is said not to become yellow with age (though it is scarcely old enough to determine that point), and is superior to amber and other more or less valuable materials, because it can withstand a sharp blow or a fall. Celluloid, too, from its ability to withstand the "weather" and frequent washing, is coming into use for many other purposes, and is surely supplanting ebonite, or vulcanite, whenever it is required to bring metal into contact with it, as sulphur is entirely absent from its composition. The latest application—a promising one, too—is the use of celluloid for casting stereotype plates for printing. These plates have already met with a favourable reception in the United States, as they are light and elastic, take ink freely, and yield a clear impression, while they do not "batter" readily like metal, and can be sent through the post or by train with the minimum of packing. For colour-printing celluloid surfaces give excellent results, for the material is not affected by the pigments, as copper electrotypes are, for instance, by vermilions, nor by the lye, benzoline, or water used to cleanse them, while the time occupied in casting and mounting them does not exceed that now required for producing a plate in stereo metal. For some time the applications of celluloid, although very various, have been confined to uses in which positive advantage could be shown over the material displaced: it is not unlikely that its comparative cheapness and the facility with which it can be worked will conduce to a still more widely-extended use of this very valuable product, many of the applications of which are set forth in Vol. XXIX., p. 154.

AMATEUR ENLARGING ON A SMALL SCALE.*

By J. TRAILL TAYLOR.

THE problem of a simple and easy mode of enlarging for amateurs, as regards the lighting department of the operation, is still open to receive more attention.

I am the fortunate possessor of several oil lamps, whose fine Greek names do not sufficiently counterbalance the trouble in trimming the wicks (which in some instances are many), the great heat, and the unpleasant smell. Could an enlarging lantern be lighted with common gas, then, indeed, would all troubles cease; but carburetted hydrogen gas, as supplied from the company's mains, is frequently deficient in illuminating qualities in a lamentable degree.

It is, however, well known to all of us that house gas may have its luminousness greatly intensified by mixing with it the vapour of some one or other of the numerous hydrocarbons. This subject has been brought before the world at various intervals during thirty years or more, and a greater or less degree of success has attended individual instances of the application. It is this system of illumination which I have thought might fittingly be impressed into the service of the photographer who, without having the mess with charred wicks and oil every time he wishes a light, might desire his appliances reduced to a gas-burner, and the whole preparation reduced to connecting a rubber pipe with the nearest gas bracket.

Of the various systems employed for more thoroughly carburetting gas, that which I bring before your notice is one of the Albo-carbon *genus*. I purchased it at one of our London shops for 8s. 6d., and having had it in use for some time can speak of it very favourably. Its principle consists in a piece of metal being placed above the gas flame, and which, thus becoming heated, conducts the heat to a chamber behind, which contains a hydrocarbon that vapourises at a temperature of 150 or more.

The arrangement is such that either the gas in its primitive state, or after it has been enriched to saturation may be emitted at the jet, and, without having had recourse to photometry to determine the advantage, it appears to me that the intensity of the light is increased fourfold.

But in order still further to obtain the highest advantages offered by the system, I have had this modified burner constructed in which two flames are employed, one being about an inch behind the other, with an air space between. This is essential to success in obtaining the best effect.

[The speaker then exhibited and explained the construction of the gas-burner to which referenee had been made. By means of a socket which had a thread similar to any ordinary gas-burner, this one could be lifted in or out of the enlarging lantern immediately, and by previously warming the reservoir, so as to initiate the vaporisation of the "albo-carbon" inside the light, assumed its energy in half a minute after being ignited. He spoke of the disadvantage of dimensions in the flames; magnitude, he said, was not compatible with the highest definition. Hence, having first secured the required brilliance, he interposed a screen or diaphragm between the lantern condensers and the flame, and as close as possible to the latter. The aperture in the diaphragm was circular, and it varied from ½in. to 1in. in diameter, the smaller one giving greater sharpness to the enlargement than the other. The position of the diaphragm was such as to hide all the light save a very bright portion selected from the most luminous part of the flame. He found it also advantageous to insert immediately in front of the diaphragm a small plano-convex lens, which prevented some loss of light by concentrating it upon the lantern condensers, at the same time that it permitted the light to be brought a little closer to them.

* A paper read at the Photographic Conference. From the *British Journal of Photography*.

HOW TO INSPECT A WATCH.

IN adjusting a cylinder watch we should first attend to the case and the parts intimately connected therewith, for the case-snap, and the fastening at the pendant may be defective. If the snap moves too hard, as is generally the case, this defect is to be corrected, when the movement has been taken out, with a small mallet, the blows of which are directed upon the bottom bezel near the joints. When the bottom is being opened, it will often be seen that the winding-post and hand-square, as well as the cups, project. They should be level with the dust-cap, because a pressure from the bottom of the case on these parts might cause the watch to stop, or, at least, make the rate irregular. Since these defects cannot all be corrected at once, it is advisable to note them upon a slip of paper, or impress them upon the memory, that they may be corrected in regular order as each part is taken in hand. Next open the dust-cap to see whether the barrel and balance have free shake in the case, and whether the closing of the dust-cap is interfered with by a bridge or screw, a condition which is easily ascertained by putting a little rouge on the suspected parts, and then closing the cover. When opening the crystal bezel we must observe the position of the hands to each other. It is necessary sometimes to raise or lower the hour-hand; the centre-staff must not touch the crystal. When defects of this kind cannot be corrected at once, they are either to be borne in mind or noted upon paper, as already advised, so they will not be forgotten. When the dial has been taken off, observe whether anything stands higher than the plate. The screws, barrel-arbor, and stop-work of low-grade watches are invariably higher than they should be, and the touching on the dial of the movable parts, such as the minute-pinion and stop-work, often causes the watch to stop. The pressure of the screw-heads, screw-ends, and barrel-arbor against the dial is apt to cause it to break.

The movement is now to be taken out of the case, and the case-snap set in order if it is found defective. Before we take down the movement a general inspection should be made. Various questions present themselves to the adjuster. How do the barrel and balance stand to the centre-wheel? Has the balance-spring free shake? Does the fourth pinion as well as its arbor approach very close to the balance? These questions can all be answered by this inspection, which will save much time if it is thoroughly done. We have now progressed sufficiently far to take down the movement and commence the actual work. The order in which the parts are examined and treated varies much among workmen. The majority begin with the train, then put in the escapement, and end with the barrel and its parts. This method is good enough; but it would be incorrect to commence with the escapement, because both the centre and 'scape wheels frequently stand out of truth, and exert a harmful influence on the position of the cylinder and the balance. I am accustomed to work according to the following method, which I think the best, although I am sometimes compelled to adopt the former. The labour required to bush and upright the centre-wheel and barrel being about the same, I take these one after the other; next I proceed to the small wheel-work, leaving the escapement until the last.

After all the parts, up to the centre-wheel, have been taken down, see whether the latter stands truly upright to the plate. In most cheap watches it does not, and is a great defect, because if not thoroughly corrected, it may cause trouble, even when the watch is about to be delivered as "ready." The hands will barely move with sufficient freedom, especially if the watch has a second-hand. The hole in the plate is frequently taken as the standard, and the whole in the bridge centred by it. This is not correct, because it invites a new error. It is certainly advisable, before commencing the bushing, to satisfy yourself of the condition of the barrel depthing, which can, at this time, be corrected with ease, and be placed deeper or shallower, as may be necessary, although the dial-hole must never be left entirely out of view. We now know what hole is to be centred in favour of the barrel depthing. The wheel is then taken down, and the quality of the pinion examined—that is, care is taken to see whether, when placed upon a tapering-tuning arbor, it will run true, whether the pinion leaves have the correct shape, whether they are too thick, and in what condition the pivots and shoulders are. These pivots, which are subject to a strong friction, must be treated with care. Pivots without polish are ruined in a short time, and spoil both the jewel holes and the oil. A composition file and rouge, or a depthing tool specially prepared for this purpose, will give them the desired polish. Having ended our labour of inspecting and taking down, we can now apply correctives to the parts requiring them.

G. Voget (in *Jewellers' Weekly*).

GUMS AND PASTES FOR LABELS.

IT is usually found that the addition of acetic or nitric acid to gums, glues, or pastes will make an efficient adhesive for almost any purpose; but the following notes by Mr. L. Eliel, read before the American Pharmaceutical Association, may be useful. Mr. Eliel says:—The formulas here presented are not original with the writer, but have been in use by him for many years with entire satisfaction. 1. Gum tragacanth, 1 ounce; gum arabic, 4 ounces. Dissolve in water, 1 pint; strain and add thymol, 14 grains, suspended in glycerine 4 ounces; finally add water to make 2 pints. This makes a thin paste suitable for labelling bottles, or wooden or tin boxes, or any other purpose which paste is ordinarily called for. It makes a good excipient for pill masses, and does nicely for emulsions. The very small percentage of thymol present is not of any consequence. This paste will keep sweet indefinitely, the thymol preventing fermentation. It will separate on standing, but a single shake will mix it sufficiently for use.

2. Rye flour, 4 ounces; powdered acacia, ½ ounce. Rub to a smooth paste with 8 ounces of cold water, strain through a cheese cloth, and pour into one pint of cold water. Continue the heat until thickened to suit. When nearly cold add glycerine, 1 ounce; oil of cloves, 20 drops. This is suitable for tin or wooden boxes or bottles, and keeps sweet for a long time.

3. Rye flour, 4 ounces; water, 1 pint; nitric acid, 1 drachm; carbolic acid, 10 minims; oil of cloves, 10 minims; glycerine, 1 ounce. Mix the flour with the water, strain through a cheese cloth, and

add nitric acid. Apply heat until thickened to suit, and add other ingredients when cooling. This is suitable for bottles, tin or wooden boxes, and will not spoil.

4. Dextrine, 8 parts; acetic acid, 2 parts; alcohol, 2 parts; water, 10 parts. Mix dextrine, water, and acetic acid to a smooth paste, then add the alcohol. This makes a thin paste, and is well suited for labelling bottles and wooden boxes, but is not suitable for tin boxes.

NOTES ON THE PROCESS OF POLISHING AND FIGURING 18in. GLASS SPECULA BY HAND, AND EXPERIMENTS WITH FLAT SURFACES.*

BY H. F. MADSEN.

(*Concluded from page* 516.)

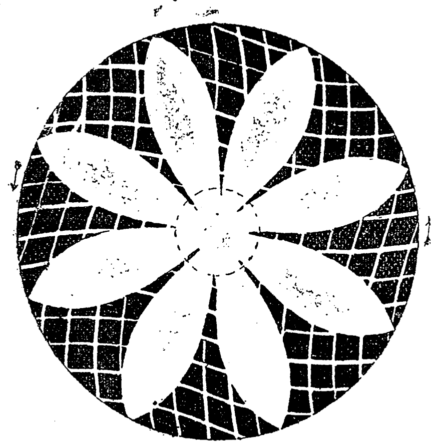
FIGURES 4, 5, and 6 represent the corresponding figuring forms of the polisher; by increasing or diminishing the acting part of these surfaces the time required can be altered. Of course the same object may be obtained by reducing the squares, as long as the given proportion is maintained.

Pitch being a yielding (non-elastic) substance, might be expected not to act similarly to a rigid surface; but still I have found Nos. 1 and 2 to give the desired result. No. 3 does not seem to answer with the weight of the glass over the polisher. (See p. 515).

The form with which the present glass was figured was No. 2.

Both polisher and glass having been regularly raised in temperature, were left together (the glass having been now and then slightly moved round its

Fig: 4.



axis) until cool, after which the usual stroke for keeping the spherical form was proceeded with for about ten minutes, when the correction was found sufficient.

In another case, No. 1 form was used upon a similar mirror, but with only 10ft. 4in. focus requiring abrasion at the edge exceeding $\frac{1}{20000}$in.

Knowing that theoretically a curve of revolution could not coincide with the polisher, except when the axis of both were in one line, this position was maintained and the glass simply revolved. By this motion rings were expected to appear, but such was not the case, and in less than ten minutes an over-corrected but true surface was the result.

The greatest inconvenience in this method is, that should the mirror become over-corrected, or a hyperboloid, the polisher must be remodelled before the spherical form can be restored. A perfectly even temperature must exist, and the polishing powder be evenly distributed, with uniform contact at every point between the two surfaces before the correction or figuring can be satisfactorily proceeded with.

Supposing, then, that in this way a regular curve receding from the sphere through the ellipsoid towards the hyperboloid has been obtained, it will next be necessary to judge the exact time when the paraboloid has been developed, and to do this nothing is so satisfactory as the artificial star, or minute pinhole test at the centre of curvature, first invented by M. Foucault. For use in this test the fourth and fifth columns of the above table have been calculated, but it was shown that in mirrors in which the length of focus exceeded twenty times their diameter, no correction from the spherical form was required, and that the amount such correction would increase in the ratio $\frac{1}{8r^3}$ (y constant), from which it would seem that this form of specula would be the easiest to make perfect.

Such is, however, not the case except within certain limits.

The rate of decrease in the amount of correction required is very rapid with the increase of radius of curvature; but the injurious effect from almost infinitesimal irregularities increases in a still higher degree, and it seems to me that even supposing that a theoretically perfect speculum could be obtained with from 20ft. to 40ft. focus, the slightest touch or variation in temperature would be sufficient to destroy its good definition

Fig: 5

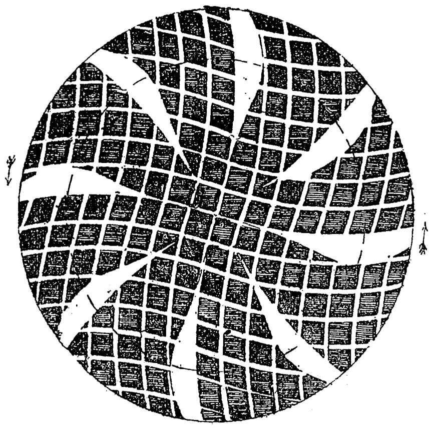


Fig: 6.

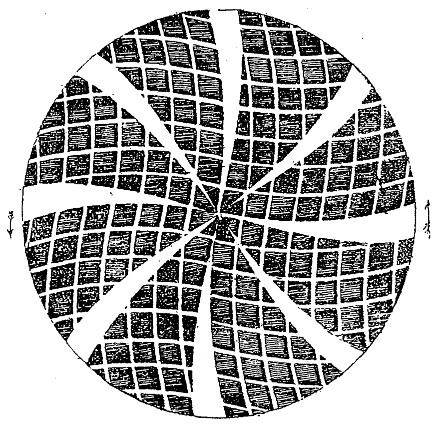

Fig 7

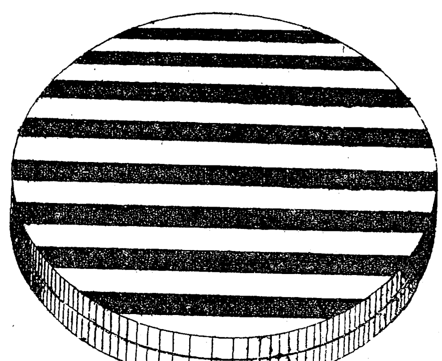


An equal film of air or perfectly flat surfaces.

under a high magnifying power, irrespective of the disturbing effect of the atmosphere.

By decreasing the focal length the rays cross at a less acute angle, and small variations in the reflecting surface have not so detrimental an effect. The correction required increases; but that does not seem to be of much consequence, so long as the proportion is not less than six to one in glasses from 10in. to 20in. diameter, as it only requires longer work in the same direction.

Such are a few of my observations during my working of these specula, and considering their weight and the care necessary to avoid the slightest inequality in temperature by handling, &c., I almost think they are the largest size that can be produced by hand; but under the same process with suitable machinery I have no doubt that much larger surfaces can be satisfactorily produced under the condition that their focal length be not allowed to exceed 20ft., or at most 30ft., which in the Newtonian construction (if required), may be lengthened by the introduction of a concave achromatic or Barlow lens.

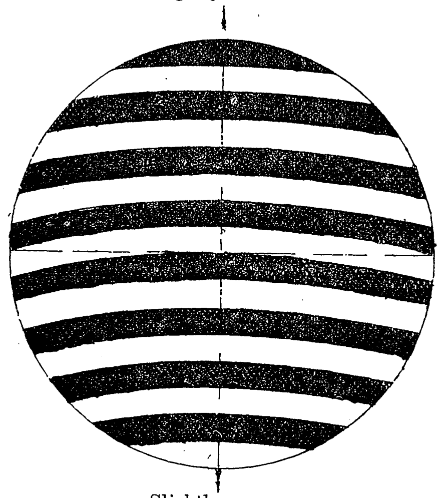
In regard to silvering the mirror, very little need be said: the process is now so well known (Brashear's method), that by ordinary attention to cleansing the mirror, equality in temperature and pureness of chemicals used, success is inevitable. (See ENGLISH MECHANIC, 11th June, 1880, p. 327.) A nearly opaque film of silver can be obtained, which, by a few minutes' polishing, becomes an almost perfect reflecting surface; but unless this can be proved to be extremely thin and perfectly even, serious injury may be occasioned to the efficacy of the reflector.

Some two or three years ago my attention was drawn to this subject by an unusually thick coating of silver applied to one of my mirrors. The definition seemed to be impaired, and the rays from bright stars to become more troublesome after silvering than before. This, it appears, was caused by the greater amount of light reflected from silver than glass; but, to prove that no change in figure had taken place, I determined to measure its thickness. The late Dr. Draper, in his work on the telescope, says: "The thickness of the silver film after polishing is about $\frac{1}{200000}$in., and variations in that amount cannot therefore cause any optical defect in the telescope.*

His results were obtained by measuring the quantity of silver deposited over a large surplus, but my intention was to compare its thickness with

FIG. 8.

Slightly convex.



Slightly concave.

the length of a wave of light. To do this I required two perfectly flat surfaces. After long and patient work, I succeeded in producing three such surfaces 5in. diameter, which by the colour test, so admirably described by Mr. Brashear in a paper read before the Engineers' Society of Western Pennsylvania, produced at an angle of incidence of 65° one uniform colour gradually changing by other inclinations, and showed by monochromatic light straight, dark, and coloured bands (Fig. 7.)

Several precautions must, however, be taken in using this test. An even temperature is absolutely necessary. The angle of observation should not be greater than 70° with the normal, but better much less, and the glasses must be as perfectly clean as possible.

These precautions refer more particularly to compound solar light. When monochromatic light is used, the test may not be so delicate, but is certainly of much more practical use, and as will be demonstrated corrrect to less than $\frac{1}{200000}$in.

When one end of the glasses is pressed, or when impurities prevent them from being exactly the same distance apart, the deviation from theoretical flatness can be judged and rigidly calculated by measuring the curve, or bends, in the bands in comparison with the distance between them, which should be as large as possible, say, from ½in. to ¾in. (Fig. 8).

For, let A (Fig. 9) represent two glasses 5in. diameter placed together and illuminated by a homogeneous yellow light (wave length = λ =

* A paper read before the Royal Society of N.S.W., July 7, 1886.

* This has lately been doubted by one of the leading opticians in a letter to the ENGLISH MECHANIC; and in the last number of that paper it has been giveen by one writer as 1-200th of an inch, perhaps (?) a misprint, 4/6/86.

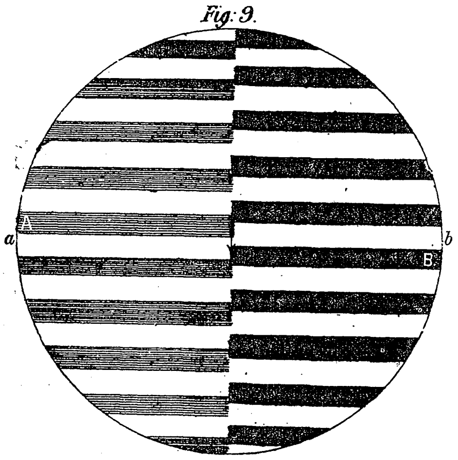
$\frac{1}{44000}$) at an angle of incidence ϕ of 30°, then from optics it is known that the dark bands appear whenever the thickness of the film of air δ is $= \frac{n}{2} \lambda$ sec. ϕ and the bright ones at $\delta = \frac{2n-1}{4} \lambda$ sec. ϕ, and that consequently the deviation in thickness between two dark bands is expressed by $x = \frac{\lambda}{2}$ sec. ϕ, so, if thus a curve in the middle band were by measurement found to be $\frac{x}{2}$ the deviation from flatness in one or both of the glasses would be $\frac{\lambda}{4}$ sec. ϕ = 0·0000065; and, as even a much smaller displacement might be observed and measured, defects of less than $\frac{1}{300000}$in. can be seen. Having thus obtained my measuring scales, my silver film was estimated in a similar manner to the above.

An ordinary film of silver once repeated was deposited upon one of the glasses, and a part of it afterwards removed by strong nitric acid. When the bands were next examined at an angle of 30° they were found to be broken or displaced at the edge of the silver, a distance about $\frac{2}{5} x$ (x = to distance between two succeeding bands).

The thickness of the silver δ would be thus expressed by $\frac{\lambda}{5}$ sec. 30 = 0·00000525, a quantity nearly agreeing with that given by Dr. Draper. Several similar measurements of single silvering or films gave results less than $\frac{1}{300000}$in.

The experiment was repeated with similar results, but on account of the excess of light reflected from the silver, part of which can only interfere with that reflected from the lower surface of the glass, the bands were difficult to be observed.

Fig. 9.



a, silver; b, glass.

The above expression might have to be added to any number of half wave-lengths $\frac{\lambda}{2}$ sec. ϕ, but that such was not the case was proved by using compound solar light.

By repeated silvering, or by using a stronger solution, the film might be considerably augmented; yet it may be concluded that by ordinary care in the polishing no optical change will be produced in the reflecting surface.

To ascertain the exact effect produced by heat and pressure upon these glasses, I placed them as before upon a wooden chuck, 2in. diameter, and observed a uniform colour at 65°.

I then placed my finger, touching without pressure, upon the centre of the top glass, and watched the effect. Almost instantaneously the colour changed to regular concentric rings continually diminishing in size but increasing in number by additional heat.

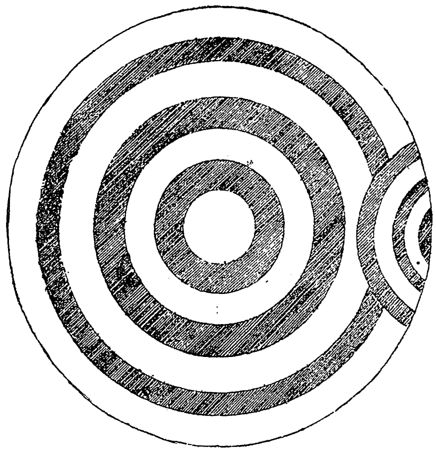
By lowering the point of sight these rings (Fig. 10) travelled towards the centre, proving the glass to have become concave, and that by a measurable quantity. At first glance, this augmentation in the film of air immediately below the point to which heat was applied might be thought to have been caused by its excessive expansion in comparison with glass. This is, however, not the case; the glasses were unconstrained, and if one part of the air between them expanded, it would only be the cause of lifting the glass equally throughout.

When the heat was removed to any other part above the top glass the same effect was produced, the lower surface becoming hollow at that point; but when the heat was placed in closer contact with the other surface, as at one end of a diameter, or at the edge, B (Fig. 10), the very opposite was the result; both glasses expanding approached nearer and nearer to each other until no light was reflected.

From this it appears that, when heat is applied at the central part of one side of a round piece of glass, the other side contracts and becomes hollow in a regular curve from edge to centre, and that such an effect will continue for some length of time, it having been observed to do so in this experiment during 10m. or more.*

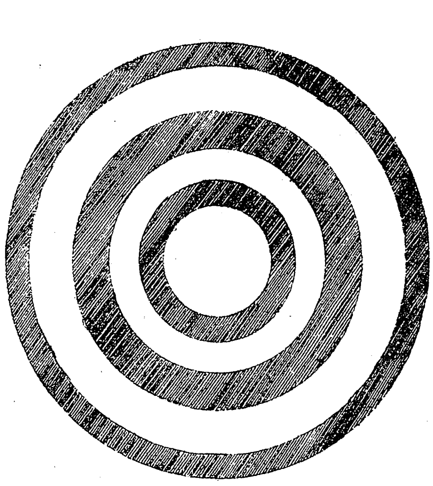
It may also be noticed that when the source of

Fig 10



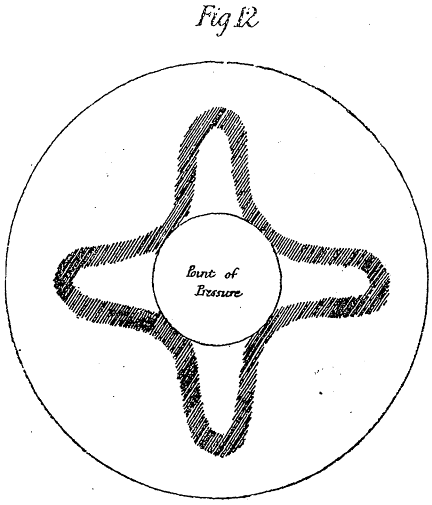
Concave (by heat).

Fig 11



Convex (by cold).

Fig 12



Pressure.

heat was removed it only occupied 2m. for the glass to return to its normal state, and that the thickness of the glass was $\frac{3}{8}$in.

* This result is what ought to take place. Heat applied at one side of the glass causes the molecules near the point of contact to expand; but it cannot pass through so bad a conductor, and consequently those in the lower side are pressed together, and the glass becomes hollow.

The glasses were next removed from the wooden support to an iron one of the same shape, and although this had been kept in the same room, yet the chill from the iron was enough in less than 1m. to produce convexity in the middle surfaces to the extent of $\frac{1}{30000}$in., but also in a regular curve (Fig. 11). A pressure of 8lb. was next applied to the same central part of the glasses, when the colour began to change, but in a different manner to that produced by heat.

Two wide bands of colour (Fig. 12),* appeared, reaching nearly to the edge of the glasses, and crossed in the middle, showing that they had become strained in two directions, and their figure completely destroyed.

This shows that although pressure has to be avoided, yet the regularity in temperature is the most important factor in the production of the true glass surfaces, and that in finished specula (particularly with long foci) a very small inequality in the temperature of their sides will produce serious defects in their defining power. It also shows that a material of small heat-conducting power would be the most desirable for the mirror to rest upon.

In conclusion, noting the regular contraction of the lower surface towards its centre, it has occurred to me that it might be possible to employ heat as an agent in the figuring of mirrors, but I have not yet tried the effect.

Since this paper was transmitted to the Society I have received the last monthly number of the ENGLISH MECHANIC, in which I wish to draw attention to two articles. One, let. 25,603 (p. 148, Vol. XLIII.), by Mr. Brashear, in which the writer expresses the same opinion as I have, in regard to the practical superiority of employing a monochromatic source of light in the testing of flat surfaces; and another, let. 25,499 (p. 80, Vol. XLIII.) by Mr. Wassell (author of a long series of valuable papers on Glass Specula), in which my conclusion as to the thickness of the silver film seems to be doubted, and is sought to be disproved.

He says: "The fact that a thick film will receive a scratch that becomes visible by reflecting light from its sides, proves that the silver film is thick enough to perceptibly allow a deviation from the figure of the surface below."

I do not maintain that variations even in the thickness of the film, as deducted by me, cannot, by polishing, be carried so far as to cause perceptible alteration in the figure of the speculum; in fact, that such can take place will at once be apparent by examination of the table for corrections as given in this paper; but, as to the visibility of the scratches proving anything in regard to the thickness of substance in which they appear, seems doubtful. Supposing the least particle which can be perceived by natural vision to be more than $\frac{1}{2000}$in., it follows that whether the thickness of the film be $\frac{1}{2000}$in. or $\frac{1}{200000}$in. the depth of scratches could not be seen; nor do these appear to our view as stated, by the light reflected from their sides, but simply by the width of the silver removed by them, and the consequent exposure of the less reflecting surface below.

Flames 350ft. high.—Not long ago, telegraphs the St. Petersburg correspondent of the *Times*, the town of Baku was threatened with partial destruction by the sudden outburst of a natural naphtha fountain, which swamped a number of buildings, and for some days was quite unmanageable. Now a volcano of earth and hot mud has broken out about ten miles from the town on the Lok Batan, close to the Ponta Railway Station, and on the night of the 15th of January the inhabitants of Baku were alarmed by a shock like that of an explosion, which made all their window panes tremble violently, whilst towards the south-west the sky was illuminated by an intense light, as of some terrible conflagration. A similar phenomenon occurred on the following night. It was soon discovered that an eruption from Lok Batan had taken place, and the following information was furnished by the railway officials of Ponta Station:—"Quite suddenly, at eleven o'clock at night, the noise of an explosion was heard, and the summit of Lok Batan shot up an enormous column of fire some 350ft. high. The whole country was instantly lit up brighter than day, and the heat could be felt at nearly a mile from the crater. There was scarcely any wind, so that the column continued to ascend quite vertically, carrying with it, as could be seen, large dark substances, which appeared to fall again into the volcano. This lasted with short intervals of subsidence all through the night and the following twenty-four hours, but luckily the matters ejected did not reach the railway station. The volume of muddy liquid thrown out is estimated at half a million cubic *sojenes*—the Russian *sojene* equalling 7ft.—and has spread itself over more than a square mile to a depth of from 7ft. to 14ft."

* Figs. 10, 11, 12 best shown under compound solar light.

SCIENTIFIC SOCIETIES.

ROYAL ASTRONOMICAL SOCIETY.

THE annual general meeting was held on Friday, the 11th inst., Mr. J. W. L. Glaisher, president, in the chair.

General Walker asked the leave of the meeting to withdraw the name of Miss Pogson, who had been nominated for election to the Fellowship of the Society. On behalf of the other two Fellows who had joined with him in nominating Miss Pogson, he stated that they desired to postpone her nomination until the question of the eligibility of ladies for election to the Society should have been decided.

Leave was given to withdraw the nomination.

Mr. Bryant read the auditor's report, which stated that the Society's balance at the end of the year was £459 9s.

Capt. Noble said: I wish to ask a question of the treasurer. In the estimates passed in the House of Commons, either in October or November last, I noticed that there appeared an item of £24,000 for the learned societies. It was passed without any remark in the House of Commons. I have already had an inquiry made at the Geological and another learned society, and find that they obtained no part of the money, and I should like to ask Mr. Common whether this society received any part of it?

Mr. Common said: I am not the Chancellor of the Exchequer, and cannot answer for his accounts. Perhaps the sum which Capt. Noble refers to is that which was expended for the maintenance of the public buildings occupied by the learned societies. No part of the £24,000 fell into our hands as money; but probably some of it reached us, as it is a part of the duties undertaken by the Government to look after the outside of our building and maintain the structure.

Mr. Ranyard: I think that I can answer Mr. Common's suggestion as to the sum mentioned going for repairs. Our external repairs are done by the Department of Works, and the £24,000 did not go to the Department of Works or to the Commissioners of Woods and Forests. It was voted direct for the learned societies; but I do not understand how such a large sum is made up. The Royal Society gets some; but we get none I am thankful to say, and I hope, for the peace and quietness of the society, that we may never get any. (Laughter.)

The secretaries then read parts of the council's annual report on the progress of astronomy. Eleven minor planets were discovered during the year 1866, and six comets, including the periodic comet of Winnecke; of these six, three were discovered by Mr. Brooks, of Phelps, New York. The various paragraphs of the report having been shortly referred to by the secretaries, the president read his address on presenting the gold medal of the society to Mr. G. W. Hill, of Washington, for his researches on the lunar theory. The president stated that Mr. Hill had very ingeniously applied some of the methods of modern mathematics to the lunar problem. Amongst other things he had made use of an infinite determinant. By a curious coincidence, Prof. Adams had also made use of an infinite determinant in discussing another lunar problem. Prof. Adams's investigation had not been published, and consequently Mr. Hill's investigation contained the first application to a physical or astronomical subject of such an instrument of research. On examining the infinite determinant made use of by Prof. Adams, it turned out to be identically the same determinant as that discussed by Mr. Hill; so that no doubt this infinite determinant had some connection with the physical problem which was not yet altogether clear. Having given the gold medal to Dr. Huggins to forward to Mr. Hill, with the best wishes of the Society for his further success, the President called on Mr. Ranyard to move an amendment of the by-laws, of which he had given notice.

Mr. Ranyard said: The resolution of which I have given notice is, "That the following words be added to By-law 75, 'nor unless the nominee selected be a foreign astronomer not resident in Great Britain.'" By-law 75 reads at present: "No medal shall be awarded in any other way than in the manner and at the time above described, nor unless three-fourths at least of the members of the council shall agree thereto." My motion would make it read — "nor unless three-fourths at least of the members of the council shall agree thereto, nor unless the nominee selected be a foreign astronomer not resident in Great Britain"; that is to say, that in future medals shall not be given to astronomers resident in Great Britain. I should like to ask your very patient consideration of the matters I am going to lay before you, because this is a self-denying ordinance. I know that I am going to ask you to go against the stream of inclination. I feel I have a difficult matter to urge; but the question is a very important one. I am going to ask you, as a fountain of honour, to behave like all other fountains of honour, and not on any occasion to bestow the medal on yourselves or on anybody connected with you. The House of Lords does not make lords. At the Bar all distinctions are conferred by an outside authority. From our schooldays upward it has been the same thing with our prizes. I believe Captain Noble will confirm what I say that county magistrates, when they grant licenses, if they are in any way connected with the grant, whether as landlord or even in the most indirect way, think it is necessary to stop away; and so it is on the judicial bench. If a Judge is concerned in a case, he immediately withdraws. It has long been recognised as only consistent with his dignity to do so; and for the dignity of this society I urge that we should do the same thing. We should put ourselves entirely above suspicion, like Cæsar's wife. We shall make a better choice, too, if we do so; for a prophet is never esteemed in his own land. There are all sorts of proverbs one might quote to show that a man in his own family is either over-estimated or under-estimated. We never form as just a judgment about those who are immediately associated with us as we do of those who are at a distance. Last year I said we could only judge fairly of those who had lived long before us. I do not go so far to-day; but I say with regard to those who are immediately connected with us, there may be jealousies or there may be friendships which may upset our judgment, one as much as the other. There is only a small body of workers at any particular science, and there is a tendency to form cliques that upset the scientific spirit; and if the scientific spirit is upset, the work will be upset. I believe that people do better work when they do it with the highest and best motive, and without any personal interest in view. Last time the only argument that was urged in favour of medals was urged by Mr. De la Rue, who can put a case as well as any one, and very cleverly it was urged; but all that he could say was that it was a pleasure to us to give medals—that it was such a privilege that we could not give it up. Now, I do not think that is an argument at all.

Mr. Common: I rise to order. Mr. Ranyard, in quoting Mr. De la Rue, is not giving his words. Mr. De la Rue said that the Society, in giving medals, was honouring itself as much as honouring the recipient of the medal.

Mr. Ranyard: I do not want to misrepresent Mr. De la Rue. I think he said that in addition to what I have stated.

The President: The words he used were, I think, that it was a graceful act of recognition.

Mr. Ranyard: At all events, we cannot say that because it is a pleasant privilege to give medals, therefore we should go on giving them. The only sort of argument that I can recognise is that it is good for our science, or that the society is better for it, and that the individual workers do better if they think there is a chance of gaining the medal. But it seems that that cannot be urged. That was universally agreed to by the medallists present last year. Anything which promotes jealousy amongst specialists must do harm, and there is great urgency in the race for the hall-mark the medal is supposed to give. Some workers feel it very acutely indeed. I do not wish to take any English instances; but I will give a few French instances at the beginning of this century. Arago was a pleasant biographer, who never said anything unpleasant, if he could help it. He tells us of men struggling earnestly in France and being upset for the whole of their lives and soured by the struggle for such rewards. He speaks of Fourier, who gained the great mathematical prize of the Academy for his great work on the "Conduction of Heat" in 1812. There was some criticism in the address that was given on the occasion of presenting the prize, and Arago says:—"Fourier never admitted the validity of this decision. Even at the close of his life he gave unmistakable evidence that he thought it unjust, by causing his memoir to be printed in our volumes without changing a single word. Still, the doubts reverted incessantly to his recollection. From the very beginning they had poisoned the pleasure of his triumph. These first impressions, added to a high susceptibility, explain how Fourier ended by regarding with a certain degree of displeasure the efforts of those geometers who endeavoured to improve his theory. This, gentlemen, was a very strange aberration of mind of so high an order." Some persons imagine that people who study science are necessarily above all human feelings; but it is not so. (Laughter.) I am glad to hear that laugh, because that is a great point in the agument; the advancing of science is done by men who are frequently, in other directions, comparatively weak men, and we ought to do everything to prevent their weakness coming up; and it will make it easier for all workers if these distinctions are abolished; they will then be juster to one another, and will lead healthier and better lives. Arago, in speaking of Malus, the discoverer of polarisation, after stating that he was not a member of the Academy, and that he had been in the army and had fought in Egypt and elsewhere, says:—"Among the candidates there was conspicuous an engineer of roads and bridges, who had also borne a part in the Egyptian expedition, and *whose connections with the Academicians were numerous and of old date.* Everyone, therefore, foresaw that the place would be vigorously contested. On the day of election, August 13, 1810, one of Malus's friends undertook to bring him the news of the result the moment it was known. But, by an unfortunate combination of circumstances, the scrutiny was not opened till a later hour than usual. Malus obtained thirty-one votes, his opponent twenty-two. The friend alluded to did not lose a moment in going to announce the result. But the usual hour at which the news ought to have reached him having long passed, the great physicist believed himself to have been defeated, and abandoned himself, in spite of all the consolations which his wife afforded him, to the deepest despondency. Thus the intrepid soldier of the army of the Sambre and Meuse; he who had seen the near approach of death at, &c., &c., allowed himself to yield and sink under the supposed want of success in an election of the Academy." It is a thing that upsets men, this striving after the hall-mark of their fellows, and this proposal of mine would take that difficulty out of the way. Perhaps we are not so fond of decorations as the French, and, if so, it is all the easier to give them up. There is just one other quotation from Arago that I should like to read, to show how considerations with regard to membership of the Institute upset Arago's judgment. He had written a life of Fresnel. It was at a time of great political excitement in France — and Fresnel had his political allies—a minister did not patronise him because he was on the other side politically, and Arago was begged to take some lines out of the éloge of Fresnel. Some of his friends urged him thus: "If you execute your project, they said to me, the Institute will be abolished; now, have you, then, the youngest member of the Academy, any right to provoke such a catastrophe? And to support this remark they pointed out to me several savants whose sole livelihood lay in their appointment as members of the Institute. These observations, strongly represented, shook my determination." Arago did modify considerably his judgment because of these strong feelings. It would be very much better to let people rely on their work than on a hall mark. A man really does get a great deal of honour from his work if he does it honestly and well; and it is as well to keep people looking to their work and to their own consciences rather than to popular applause for the reward of their work. I don't think that can be doubted. Last year it was pointed out that scientific work was not done for the medals. I do not think it is; there is something else which pushes men forward; and therefore these medals do not make men work. I say it hinders work, and I should like to hear what can be said for the system not hindering work. The men who get the medals fairly do not get them till they have earned their laurels, and do not want the patronage, and if they do want the medals it is a pretty good indication that the medal has been wrongly given.

Mr. Franks: I have great pleasure in seconding the resolution which has been proposed, not merely as a matter of form, but because the proposal has my hearty sympathy. I think by limiting the award of medals to foreigners we shall raise the *morale* of the Society; and with regard to ourselves, if we can be magnanimous enough to set the example, we may very well leave our scientific men to the tender mercies of foreigners.

Prof. J. C. Adams: I would crave a few remarks on the present proposition. It seems to me that, logically, if Mr. Ranyard makes this proposal seriously, he ought to carry it far beyond the point which he stops at. He ought not to say we ought to confine our medals to foreigners; but that we ought not to give any medals at all. Why should we demoralise foreigners (laughter) by proposing them for medals any more than we demoralise our own people. Therefore, I should propose, instead of Mr. Ranyard's proposal, to enlarge the scope of it. Besides that, we ought clearly to be logical. Even if we admit foreigners, we ought not to admit any of our foreign Associates. There are a number of them, and generally we have picked out the most eminent men we can find to make them Associates; but we ought, at the same time, to say, "Remember, by electing you an Associate, we render you incapable for ever of getting any medal from us." That does not appear on the face of it very rational. As to the idea of demoralising our own people by giving medals, when they have done their work, not for a medal, but for the pleasure of doing it and for the benefit of science, then to pick out such men as are worthy and present them with the medal, cannot demoralise them. I do not think Mr. Hill, who did his work ten years ago, will find himself very much demoralised

When he wrote his valuable paper, of which we have had such an interesting account, he did not think about getting a medal for it, and if he had, he probably would not have got the medal. We should not have picked out a man whose object in writing a paper was to get a medal. We pick out a man because we think he has done his work worthily, and we have no doubt he had a good motive in doing his work. If we do not give medals we shall suffer in one way, as we shall not have the pleasure and advantage of listening to such an admirable address as we have had to-day from our president.

Captain Noble: I am disposed to move an amendment to Mr. Ranyard's motion. I think that as good work has certainly been done in England as has ever been done abroad, both in mathematical and observational astronomy, and I do not see why if foreigners are to have medals, Englishmen—if they earn them—should not have them too. But I agree with one thing which fell from Mr. Ranyard, that, like Cæsar's wife, we should be above suspicion, and I think we might do this. There is a rule in the Geological Society that no member of council can receive a medal so long as he holds office, and that rule has been found to work very well. I think we might go as far as that, and say we would not give a medal to one of our own body so long as he was holding office. But beyond that I would not go. If the meeting is disposed to accept that as an amendment, I would propose it.

Mr. Sadler: I will second the amendment.

Mr. Nightingale: I should like to say a few words on this question. There is no doubt that in a Society like this, where the council is made up of the very best men, a large number of medals must of necessity fall to the members of the council. Thus we have the curious position of the council giving medals to itself, so to speak. I think there is no other instance in the world in which such a curious state of things exists. It is like the Wranglers of Cambridge meeting and settling between them as to who is to have the prize. It seems totally anomalous to me. I have always had the idea that whether they are dignities, decorations, or promotions, or any kind of reward, there should be some outside person, some superior individual or individuals, to settle the claims of the various applicants. There is no case in which the recipient, or the prospective recipient, of an award sits on the committee which votes that award. If that is so, it necessitates serious consideration by anybody who is in favour of the present system, and they must show very cogent reasons why the rules of this society should support such an extraordinary anomaly. Mr. Ranyard has put it very clearly that there may be friendship amongst members, and if the council awarded the medals, there will always be some personal feeling among the most scientific people that ever lived. Why risk the dignity of our society? Why run the slightest risk that anything should be imputed against the society for the mere sake of what I might almost call tinsel decorations of really sterling merit? What is this medal? Its value is purely the work it represents. That work surely can stand alone. If the work is good it needs not a medal to support it. If the work is indifferent the medal gives it a fictitious value. It is, as Mr. Ranyard says, a sort of hall-mark. But is it advantageous as a hall-mark? Is there any evenness in the regular standard by which the award of medals is made? It is arbitrary to a degree. It has therefore a very indifferent value as a hall-mark. What, then, is the merit of the medal? It has been admitted on all hands that it does not encourage work. Everyone seems to say so, and surely there is no member who wants the medal as a trade mark. What, then, can be the use of it? If it is liable to introduce jealousies and party feeling amongst the members; if it is liable to set members who would otherwise be friendly at loggerheads, why carry on this procedure? There is a sort of feeling about it to me that a medal is as for schoolboys—a sort of prize. It is fit to excite the ambition of a schoolboy; but that is not the object of it in this Society, and I have never yet discovered that any other reason was given for awarding prizes. Under these circumstances, though I think the amendment has a great deal to be said for it, I shall support the original motion.

Mr. Ranyard: Prof. Adams asks first, if I mean the motion seriously. Certainly I do; very seriously. It is an unpleasant motion to press, and I should not have undertaken it unless I considered the matter a very important one for the improvement of the society, and for the advance ment of astronomy. Prof. Adams says we ought to extend the motion to exclude Associates; I do not follow that at all, because Associates have no vote. I simply said, "Cut out all those from receiving the medal who have a right of voting for it"; therefore, Mr. Hill would not have been cut out, and therefore we should not have lost the interesting address of the president to-day. I say this, though I should be inclined generally to speak against *è loges*, especially speeches in praise of those with whom we are immediately connected—for there is a very small circle of workers at any particular science, and they are apt to say things too highly in praise of one another, or to detract from their neighbours.

Capt. Noble's amendment was then put, and lost on a show of hands, though there was a considerable minority for it. A smaller minority held up their hands for Mr. Ranyard's motion.

The list of names proposed by the late council for officers and council for the coming year was carried without any alteration.

WESTERN MICROSCOPICAL CLUB.

ON Monday week the club met at the house of F. Crisp, Esq., LL.B., the well-known secretary of the Royal Microscopical Society. After due attention to the tea-table, adjournment was made to the conservatory. Here, by an ingenious arrangement of mirrors and rock-work, plants and animals appear perched on inaccessible heights, or seemed placed along endless avenues of ferns and lights. Proceeding thence to the museum, the vast collection of microscopes and microscopical apparatus was thrown open to the examination of the members. Mr. Crisp said it might be interesting to the members and visitors, before they proceeded to examine in detail the collection of instruments, if he were to give a general description of the collection, and of the system of classification adopted in the arrangement. Broadly stated, the collection consisted of—(I.) *Antique* microscopes and (II.) *Modern* Microscopes. The Antique Microscopes comprised the whole series known (so far as it had been possible to obtain them), from the earliest to the date of the general application of achromatism—about 1824. These, again, were divided into—(1) *Simple* Microscopes, (2) *Compound* Microscopes, and (3) *Solar or Projection* Microscopes. Of the Simple Microscopes, those designed by Leeuwenhoek must, of course, be regarded as of very special interest, for though he belonged by birth to Holland, and was hardly known to have ever quitted his native town—Delft—yet the whole of his microscopical researches had been communicated to the world through the medium of the Royal Society. The Simple Microscopes of Musschenbroek, Wilson, Joblot, Lyonet, Cuff, Lieberkühn, George Adams, sen., Benjamin Martin, and others, had each special points of interest. He might note particularly a pretty model in silver made by George Lindsay in 1742, which was the subject of the first patent specification relating to microscopes registered in England. Stephen Gray's Water Microscope was an ingenious effort to utilise lenses consisting of drops of water. A large dissecting instrument, devised by Lieberkühn, with its ghastly array of adjustable hooks for stretching out the preparation, showed that the inventor intended the microscope for service. Of Antique Compound Microscopes, that of Hooke's design (1665) stood first in the front rank of interest, by reason of its general design, and also as embodying the first application of a field-lens to the eyepiece. Then there were Italian microscopes by Giuseppe Campani, Eustachio Divini, and others, of which some might possibly be of earlier date than Hooke's. A highly ornate microscope, which had formerly belonged to one of the Popes, would doubtless attract attention. Other highly ornate instruments, made by the Duc de Chaulnes, G. Adams, sen., Culpeper, Demainbray, and sundry of unknown origin, the designs of which, however, clearly pointed to Italian workmanship, should also receive attention. The substantial improvement in the early arrangement of the focussing adjustment, initiated by John Marshall, would be observed in an excellent example of his construction; and a second model, evidently modified from Marshall's, showed one of the earliest known applications of a mirror to the microscope. Lieberkühn's "Compass" microscope was curious, both on account of its apparent fragility and as containing a considerable number of special appliances for dissecting and for viewing live objects. Of Antique Solar Microscopes, Cuff's early application of a heliostat mirror, actuated by catgut and a rod, to Lieberkühn's instrument (which previously had no mirror, and, consequently, had to be directed to the sun by means of a "scioptric ball") would be noted, and the various subsequent improvements in the mechanism for controlling the mirror, devised by B. Martin and G. Adams, and copied more or less by certain Dutch and Italian makers. The swinging tail-piece applied by W. and S. Jones to their Lucernal Microscope towards the close of the last century was interesting in showing that the principle of radial illumination was then known and put in practice, thus preceding Grubb's Sector Microscope by some 50 years, and Zentmayer's swinging tail-piece by 70-80 years, in both of which the special feature was the provision for radial illumination. Turning to *Modern* Microscopes, they had been classified firstly into the two great divisions of (1) *Simple* and (2) *Compound*. The Simple Microscopes presented so many varieties, that it had not yet been possible to subdivide them in a manner wholly satisfactory. The Compound Microscopes had been dealt with more successfully, though he could not regard the classification he had made of them as that finally to be adopted. The provisional arrangement was their division into seven classes: (*a*) *General form*, which included all microscopes that might be regarded as type-models of general design, where the makers had sought to embody a number of points the combination of which gave some claim to originality; (*b*) *Binoculars*, &c., which included all the known forms of microscopes devised for binocular vision, and to enable two, three, or four observers to view the same object simultaneously; (*c*) *Illumination*, comprising all microscopes in which the chief aim had been the application of special means to control the illumination, of which Grubb's Sector Microscope, Zentmayer's "Centennial," and Wenham's "Radial" might be regarded as types; (*d*) *Special Mechanism*, including the two sub-divisions of peculiarities in the fine-adjustment, and peculiarities in the object-stage; of the former he might mention D'Arsonval's water fine-adjustment, and various applications of catgut, and many special devices showing great mechanical ingenuity; of the latter, the double-lever mechanism devised by the late C. Varley, and a jointed-arm mechanism by Pillischer might serve as types; (*e*) *Portable*, in which the principal aim had been to render the microscopes conveniently portable, with more or less regard to the completeness of the equipment; (*f*) *Demonstration*, or Class Microscopes, where the intention was to provide a convenient instrument to be handed round to a class of students, or for carrying a number of slides for demonstration purposes, in which might be mentioned the ingenious locking arrangements of objective, eyepiece, &c., devised specially for French students by M. A. Nachet; (*g*) *Special object*, where the microscopes were designed for particular investigations, which class would probably incline to outgrow all reasonable limits, for there were already a dozen or more varieties of petrological microscopes and micrometer microscopes (of which Nobert's was especially interesting). Then there were stomach microscopes, ear microscopes, eye microscopes, frænum microscopes for observing the circulation of the blood, aquatic or tank microscopes, botanical microscopes for observing the growth of plants, vacuum or air-pump microscopes for viewing objects in a rarefied atmosphere or vacuum, and, on the other hand, a microscope for viewing objects under the pressure of 500 atmospheres or more; microscopes for counting the threads in different fabrics, for examining the toothed wheels of watches, &c., for observing chemical reactions, the fusion of metals, &c., for determining the number of vibrations of a particular note emitted by a tuning fork, a violin string, &c. (Helmholtz's Vibration Microscope), and many others, the tendency to specialisation in modern microscopy, as in other sciences, having plainly set in for the production of instruments with particular adaptations for the special purpose in view.

Referring to the large number of appliances designed as accessories for the microscope, the classification of them had not yet been completed. The illuminating apparatus included devices acting as simple reflectors (plane mirrors and prisms) and condensing reflectors (concave mirrors); simple refractors, and condensing refractors (prisms, lenticular prisms, lenses, "buttons," &c.); and, again, achromatic and non-achromatic condensers; diaphragms, and light-modifiers, &c. Then there were numerous forms of drawing prisms, micrometer eyepieces, micrometer stages, electrical stages, warm stages, mechanical fingers, frog-plates, compressoria, multiple nose-pieces, changing nose-piece adapters, and many other appliances. The visitors were then invited to examine in detail the various microscopes and apparatus, Mr. J. Mayall, jun., giving detailed explanations regarding the history and chief points of interest. These and many more unmentioned compounds of brass and glass were freely thrown open for the members and visitors to handle and examine at their leisure.

A thoroughly interesting evening was spent by the club in this unique collection of microscopical wonders. The next meeting will take place on March 7th at the house of B. T. Lowne, Esq., F.R.C.S., subject, "Mouths of Insects."

Any information as to the club may be obtained of the hon. sec., Mr. A. W. Stokes, Vestry Hall, Paddington Green, W.

THE telephone rate between Paris and Brussels is fixed at 3fr. for five minutes' conversation; and subject to a deposit of 60fr., and to the adaptation of the apparatus at his own expense, any Parisian already having a telephone can communicate direct with Brussels.

THE tomato pack of 1886 in the United States was 2,363,760 cases of two dozen cans each. This was not up to the figure of 1883, when 3,000,000 cases were produced; but it was much in advance of 1885. The annual consumption of the United States calls for about 2,500,000 cans.

SCIENTIFIC NEWS.

FROM Dun Echt Circular No. 135 we learn that Dr. Oppenheim, of Berlin, has computed the elements and ephemeris of comet Brooks (B, 1887) from observations made at Strassburg, Kiel, and Paris. T = 1887, March 18·8369 Berlin M.T.; $\pi - \Omega$ 160° 8′ 18″; Ω 280° 37′ 6″; i 103° 51′ 21″; log. q 0·20722. The ephemeris for Berlin midnight reads:—Feb. 18, R.A. 2h. 31m. 34s., N. Dec. 68° 21′; Feb. 26, R.A. 3h. 15m. 58s., N. Dec. 58° 58′; brightness decreasing. Dr. R. Spitaler, of the Vienna Observatory, makes the time of perihelion passage March 23·01985 B.M.T.

Barnard's comet (C, 1887) has been observed at Paris, and Prof. Weiss, director of the Vienna Observatory, computes its perihelion passage at Nov. 23·6302 Berlin M.T. The ephemeris for Berlin midnight on Feb. 20 is R.A. 20h. 29m. 54s., N. Dec. 42° 12·3′. The comet is now in Cygnus, and will be always above the horizon as long as it continues visible, though low down. It is becoming rapidly fainter.

From the Liverpool Astronomical Society's Circular No. 15 we learn that Mr. T. W. Backhouse finds that 28 Andromedæ is probably variable within small limits. The observations are too few to allow of any period being determined. The star is, however, of short period —perhaps of the Algol type.

According to a computation by Mr. J. E. Gore, of Ballysodare, the orbit of the binary 14 Orionis is such as to give a period of about 190 years.

We have received the first number of the Publications of the Liverpool Astronomical Society's Observatory, containing a memoir on "Photographic Photometry," in which is a catalogue of 500 stars, the photographs taken with the Grubb equatoreal stellar camera of 4½in. aperture, and another on "Spectroscopic Observations with the 17·25in. equatoreal." The Rev. T. E. Espin is the observer to the society.

Prof. Peters, of Clinton, N.Y., has named planetoid 264, discovered by him on Dec. 17 last, Libussa.

The report of the Administration of the Meteorological Department of the Government of India for 1885-6 gives an account of the establishment of a new first-class meteorological observatory at Allahabad. The total number of observatories provided with instrumental equipments in various degrees of completeness amounted at the end of the year to 131, two being in the Bay Islands, and six extra-Indian. A special object of attention has been the influence of forests on climate, and the observations made with this view greatly tend to strengthen the theory that the rainfall is greater over forest tracts than beyond them. Measures have been taken for extending the Bengal storm-warning system, a subject to which public attention was aroused by the destruction of life and property at the settlement of Hookeytolla at False Point, in Orissa, by a cyclone which passed over that place on the 22nd of September, 1885.

The death is announced of Dr. Philip Fischer, the well-known mathematician and professor at the Darmstadt Polytechnic.

The famous Indian botanist, Babu Harimohun Mukerji, of Bengal, is dead. He was at one time head-master of a small agricultural school attached to the botanical gardens of Sibpur, but left it to pursue his wanderings in search of Indian plants in the northern and eastern districts. He was the author of several botanical works.

The bankers of the Royal Society have received a cheque for £7,800 from Sir W. Armstrong. It is his contribution to the Scientific Relief Fund.

According to the *Athenæum* the *Philosophical Transactions* of the Royal Society is about to undergo a change of form. Vol. CLXXVIII. (1887) will probably be issued in two parts, one mathematical and physical, the other biological; and this division will be continued in subsequent years, so as to form two independent series. A still more radical change in contemplation is the separate publication of a certain number of copies of each paper as soon as ready for press.

With reference to his remarks in the discussion on Mr. Taylor's paper on "Photographic Lenses" (p. 517), Mr. J. Mayall, jun., has addressed a letter to the *Journal* of the Society of Arts, in which he says:—"In my remarks on Mr. Taylor's paper on 'Photographic Lenses,' which he read at the Society on the 26th January, after criticising what I considered his extraordinary misapplication of the term 'aplanatism' in using it as equivalent to 'angular aperture,' I said I did not attribute the origination of that idea to Mr. Taylor, because it had been more or less used (in that sense) in popular treatises on photographic lenses, and even in Monckhoven's work on 'Photographic Optics.' In justice to the late Dr. Van Monckhoven, I must ask you to allow me to withdraw that statement so far as he was concerned, for on referring to his work again —which had not been in my hands since 1867, the date of the English edition—I find he used the term 'aplanatism,' in its relation to photographic lenses, as Coddington and Herschel had employed it, namely, as signifying freedom from spherical aberration. It appears to me, then, that the withdrawal of Monckhoven's authority in support of Mr. Taylor's erroneous definition of aplanatism, leaves the responsibility for the adoption of the error far heavier on Mr. Taylor. On reference to my correspondence with the late M. Prazmowski, of Paris, I find the photographic portrait lens he made for me—in which he got rid of the usual separation of the flint and crown in the back combination by using flint glass in the whole construction—was made in 1868-9, and not merely 'about ten years ago;' my showing the lens to the late Mr. J. H. Dallmeyer would hence have been about 1869, and not merely 'ten years ago.'" In connection with this paper (pp. 495, 517) it may be noted that "chromatism" appears for achromatism, and "clouded fringes" for coloured fringes.

The Geographical Society of Australasia has been authorised to prefix the word "Royal" to its title.

By the terms of a Bill introduced into the Governor-General's Legislative Council, an Inventions Office will be established in India under the superintendence of the Revenue Secretary to the Government, and holders of patents obtained in Great Britain may apply for "leave to file a specification" in India within twelve months from the date of sealing of the patent here. The Bill also extends the copyright in a design to five years.

It may be of interest to some of our readers to learn that the net cost of publication up to the present of the report of the scientific results of the voyage of the *Challenger* amounts to £53,000.

According to an American contemporary, "Oxford and Cambridge professors do more original work than our [American] professors, simply because they are given the time for it." We are afraid our American contemporary does American professors an injustice.

The destruction of the remarkable terraces of pink and white silicious sinter on the shores of Lake Rotomahana, in New Zealand, during the eruption of Tarawera last June, has given rise to speculation as to the rate at which the old terraces were formed. Mr. Kerry-Nicholls states that names and dates written on the terraces, over which the silica-loaded waters poured, were covered in the course of twenty-five years with only a very delicate layer of sinter, the deposition being so slow that it would have taken hundreds of years to obliterate the writing. Mr. Lant Carpenter, however, says that the wing of a bird, shot by Dr. Hector as it was flying over the terraces, fell in a favourable spot, and became so completely incrusted in the course of a fortnight that its form was beyond recognition.

Evidence as to age always requires careful examination. The New York *Lumber Trade Journal* says that many surveyors and lawyers know that the concentric rings shown by trees are not to be taken as evidence of the lapse of time, and it gives the following as the result of an examination of pieces of wood from trees the age of which was known. Pig Hickory 11 years old showed 16 rings; Green Ash, 8 years, 11 rings; Ky. Coffee Tree, 10 years, 14 rings; Burr Oak, 10 years, 24 rings; Chestnut, 4 years, 7 rings; Peach, 8 years, 9 rings; Chestnut Oak, 24 years, 18 rings.

At the recent meeting of the Liverpool Astronomical Society, the Emperor of Brazil was elected a member, and the claim of the Pernambuco branch, which now numbers more than eighty members, to elect a local executive, was unanimously allowed.

A patent has been obtained in this country for the use of hydrofluoric acid, either in a gaseous or in a liquid form, to eliminate vegetable matters from animal fibres or mixed fabrics.

One of the tunnels which the City of London and Southwark Subway Company is driving under the Thames near London Bridge is approaching completion, if it has not by this time reached the Surrey side. The distance from the Middlesex shaft at Old Swan Wharf is 667ft., and as the shield for driving was not fixed until Oct. 28 last, it follows that modern appliances enable the engineer to drive a tunnel under the Thames in sixteen weeks. The second tunnel has been commenced, and the company are so satisfied with the work that they have sought powers from Parliament to extend the line beyond the Elephant and Castle to the Swan at Stockwell.

Lord Stanley of Preston, replying to Lord de la Warr, in the House of Lords on Monday evening, said that the subject of continuous railway brakes still engaged the attention of the Board of Trade; but he could not promise that any further steps would be taken to enforce the requirements of the circular. Much progress has, it appears, been made by the companies in the direction of securing efficient brakes, but there is great difference of opinion as to the best brake for any particular line.

Apropos this question of the brakes, a new brake, the joint invention of Mr. J. Cowling Welch and Mr. Parker-Smith was tried last week on the Hadleigh branch line near Ipswich. It is an interchangeable automatic brake, and each vehicle would be required to be fitted with two train pipes, so that the brakes could be worked on either the Westinghouse or the automatic vacuum pattern.

The new 110-ton gun has successfully withstood its preliminary trials; but it will be some time before a full report of its performance will be issued. The following are the correct dimensions:—Length over all, 524in.; length of bore, 487·5in. (30 calibres); bore, 16¼in. The breech engages in the breech-piece, leaving the A tube with its full strength for tangential strain. The A tube is in a single piece, and was supplied from Whitworth's works. There are four layers of metal hoops over the breech. The maximum firing charge is 900lb. of cocoa powder, the projectile weighs 1,800lb., the estimated muzzle velocity is 2,216ft. per second, and the estimated total energy is 61,200 foot-tons.

The White Star liner *Celtic* has been fitted with appliances for using forced draught, and on a recent run from Belfast to the Mersey the results obtained were considered highly satisfactory.

According to Dr. Eisenmann, of Berlin, a solution prepared by mixing tungstate of soda 6 parts, phosphate of soda 1 part, and water 60 parts, slightly acidulated with sulphuric acid, is regenerated by mere exposure to the atmosphere when used in a zinc cell.

The master of a Swedish steamer says that he observed the reflection on the sky of the light from the Isle of May at a distance of 46 miles from the lighthouse.

It is proposed, in accordance with Royal and Ministerial decrees, to open on the 1st of May next, at Milan, an international competition of corn driers, and especially of driers of Indian corn. Foreigners as well as Italians may compete. Two prizes are established, each of the value of 2,000 lire, with a diploma of honour for the best driers of Indian corn and rice respectively. Applications for admission must be forwarded to the Executive Commission, at the Ministry of Agriculture, Rome, by March 31st.

It is proposed to hold in London, next autumn, an international congress of shorthand writers and of those interested in the stenographic art.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of the* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE DIAMETER OF STAR DISCS.

[26833.]—THE following is M. André's formula, for which "Orderic Vital" asks in letter 26759, page 476:—"Cet agrandissement du disque central, à mesure que l'ouverture diminue, est une conséquence directe de la théorie. En effet, nous avons posé

$$n = \frac{2\pi}{\lambda}\,\frac{d}{f}\,r;$$

or, si δ est la valeur en secondes du diamètre du cercle sur lequel se trouve le point M, O l'ouverture $2\,r$ de la lunette, et A la quantité $\frac{2}{\pi}\,\frac{\lambda}{\sin. 1''}$ on a

$$\delta = n\,A\,\frac{1}{O};$$

de telle sorte que *le diamètre du disque central*, ou celui d'un anneau quelconque, *est inversement proportionnel à l'ouverture de l'objectif.* La valeur du diamètre de ce *disque central* est, pour chaque objectif, une constante caractéristique qui joue un grand rôle dans les observations qu'on peut faire avec lui. Si l'on suppose l'objectif *parfait*, son ouverture égale à 10 centimètres, et si l'on prend pour λ la valeur qui correspond au jaune, partie la plus intense du spectre, d'où

$$A = 0{\cdot}727,$$

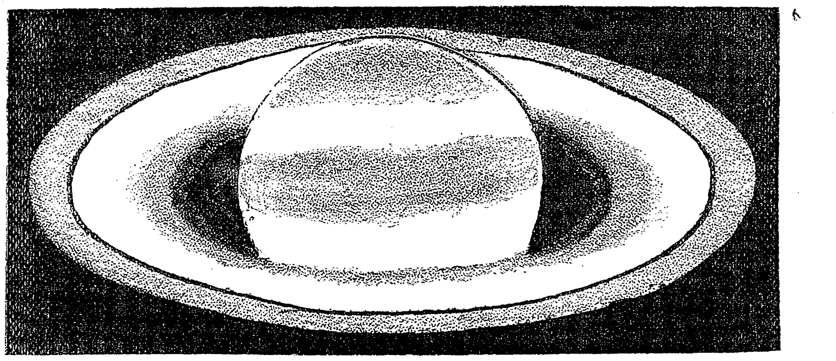
on a comme *valeur maximum* de ce disque central.

$$2{\cdot}80''.$$

On comprend, en effet, et nous le démontrerons plus loin, que ce disque lumineux nous apparaît plus ou moins grand suivant l'intensité de la source observée, ou bien le plus ou moins d'éclat du fond sur lequel on le mesure, &c." The following quotation from the Report of Durham Observatory in the *Monthly Notices* of the R.A.S., Vol. XXXII. p. 152, will be of interest in this connection:—"Some success attended an attempt to measure the diameter of the first optical ring of light round the image of the star Polaris by its transit over the meridional wires of the transit circle; but the observation, though easily and satisfactorily made, and though agreeing with a similar determination made two years ago, does not agree with the diameter which theory assigns for the object-glass employed." I cannot say whether the theory referred to is Airy's original one, or as corrected by Mr. Stone (c.f. *Monthly Notices*, XXVII. p. 303; ENGLISH MECHANIC, Feb. 5th, 1886, Vol. XLII. p. 468), as no details of the Durham observations have been published. **H. Sadler.**

SATURN—PHOTOS OF STARS AND ANONYMOUS WRITERS.

[26834.]—AS the most favourable time for observing Saturn is rapidly passing away, I send a sketch of the planet as it appeared in my 8½in. Calver reflector on Dec. 26th, powers 250 to 300, definition moderately good. The top of the ball was seen well over Cassini's division, and very nearly touched the outer edge of ring A. No part of the ball could be seen on north side of the ring. The south polar cap was dark grey, not so dark as sometimes seen, but quite as extensive; north was a broad band of yellowish light, and then a broad band of darker belts followed by the equatoreal belt, which appeared as usual. There was hardly any shadow of the ball on the rings, what there was was on preceding side. The outer edge of outer ring was not clear and distinct, like the ball, but undersized, its colour greyish, same hue as the lighter belts. Cassini's division was clear and distinctly broader at the ansæ. Ring B, nearest the division, was very bright, fading gradually into the crape ring, which was a dark blue, but sometimes it has appeared to me reddish brown: it was seen as a thin dusky line over the ball. What was especially noticeable was that ring B nearest the division was far brighter than the Equatorial belt, and was the brightest part of the whole system; the shading in the east and west ansæ nearest the

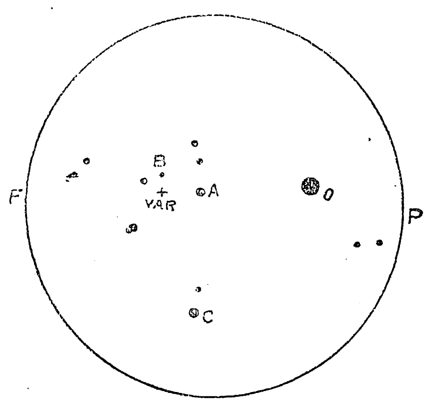


crape ring was very conspicuous. The following ansa seemed more shaded than preceding one, but on other occasions I could detect no difference. I hope amateurs will continue yearly to send sketches of the planets to "Ours," as such always interest and encourage us to observe and to report our observations, even when taken with small apertures.

I have seen no sketches of Saturn this season, and none of Jupiter last year. A correspondent asked, some weeks ago, if photographs of the heavenly bodies as recently taken could be anywhere obtained. I think Mr. Herbert Sadler replied: "None except Rutherfurd's moon photos." I am pleased to inform you that excellent reproductions of the photos of the Brothers Henry have appeared in *Knowledge.* The May number has a faithful copy of part of Cygnus; June has the Pleiades, July the nebula round Maia, October Saturn, November Jupiter. They are extremely like the original prints (which I have seen, the stars being shown white on a black background). I am sure they will delight many amateurs. The concluding paragraph of the letter of a third R.A.S. (No. 26788) I suppose is very crushing; but would it not be fairer and more English-like if the writer signed his name, so that the public could judge of Mr. Roberts's and the writer's comparative merits as benefactors of astronomy. Anyone who has read the *Proceedings* of the Royal Astronomical Society will see Mr. Roberts's work has been justly appreciated by well-known astronomers, who have thanked him personally in public. Mr. Roberts no doubt is well capable of answering for himself, or treating with silent contempt attacks made by anonymous writers. **H. Watson.**

THE NEW VARIABLE STAR NEAR THETA TAURI AND NEAR OMICRON CASSIOPEIÆ.

[26835.]—THIS star, whose variability was announced in Circulars Nos. 10, 12, and 13 of the L.A.S., is in all probability not a long, but a short period variable. It is so easily found, being in the same low-powered field with θ Tauri, that some of ours may care to watch it. It seems probable that if it is well observed a period will be found for it before it passes out of sight to the west. I there-



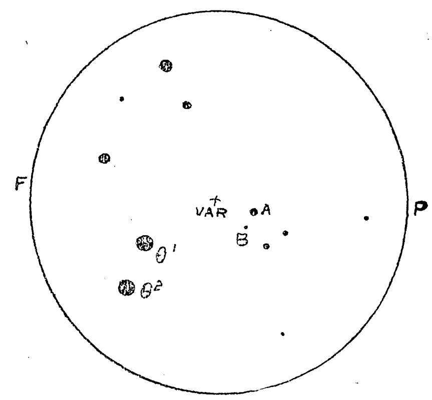
The brighter stars in field with the new variable near o (Omicron) Cassiopeiæ.
1887, Feb. 6, 17¼ equatorial, power 70.

fore venture to send you a rough drawing of the field, which will enable your readers to identify it easily. The comparison star A was estimated Feb. 2 as 10·0, while B was entered as 11·5; probably these estimates were affected by the moonlight, and are 0·5 too low; but adopting them for the time being, my observations of the variable are:—

1887.	Jan. 29	11·0mag.	Feb. 8	9·7mag.
	Feb. 2	10·5 „	Feb. 9	10·3 „
	Feb. 5	9·5 „	Feb. 10	10·3 „
	Feb. 6	9·5 „		

Mr. Gage, on re-examining his observation of Jan. 16th, does not feel positive that he observed this star; but there can be no doubt that he observed it on Jan. 22nd, at which time it was evidently decreasing in light; there seems good reason then for suspecting that it is a short-period variable. It would be hazardous to name a period at present, but probably it is about 20 days, and we shall have another maximum in that case during the last days of the present month. On Feb. 9th the star was observed by Mr. Baxendell, junior, and Mr. Gage, their estimations agreeing well together.

The other new variable star near Omicron Cassiopeiæ will be easily found from the brighter star with the help of the second drawing. The



The brighter stars in field with the new variable near θ Tauri.
1887, Feb. 2, 17¼ equatorial, power 70.

star A I suspect to be variable; C is about 8·5; while B is 10·2. Observing last night, Feb. 10th. The variable was estimated 10·6, while A was 8·6. **T. E. Espin.**

L.A.S. Observatory, Wolsingham, Darlington, Feb. 11th.

COMET B, 1887 (BROOKS)—JUPITER.

[26836.]—THE comet was seen here about 9h. 40m. and 10h. 40m. on the 12th inst., as well as on the night of the 13th, very nearly on a line between Epsilon Cassiopeiæ and the Pole Star, and apparently slightly nearer ε Cass. It was, however, a very faint object in a 4in. Dollond.

I must thank "F.R.A.S." for kindly referring me (Dec. 3 last) in connection with the self-luminosity of Jupiter, to Captain Noble's interesting observations in the *Monthly Notices.* The existence of a dull red glow would, I presume, in no appreciable way affect the apparent brilliancy of Jupiter, unless indirectly by its action on the surface, or by promoting atmospheric conditions around the planet more favourable for reflecting solar light.

Hendon, Feb. 14. **P. F. Duke.**

[26837.]—I SAW the above comet last night. It was pretty bright with the 10in., power 100. Diameter of coma, about 3′—4′, with a slight granular condensation. There appeared to be a very small star-like nucleus = about 11 mag.; but as it was in a rich field of stars, the apparent nucleus may have been a small star; but clouds coming over prevented me from ascertaining this. It is most favourably situated for observation at present. **Herbert Ingall.**

DOUBLE STARS η CASSIOPEIÆ (Σ 60) τ CYGNI.

[26838.]—IN answer to Mr. H. Sadler's interesting note on η Cassiopeiæ (letter 26566, page 322), I have recently measured the star on several nights with my reflector, as given below, and can fully

corroborate the fact of the curious similarity existing between the pairs η Cassiopeiæ and 70 Ophiuchi. Both are difficult to measure in distance, possibly owing to the inequality of the components, and in each case the smaller star is a very peculiar colour, which renders it difficult to see with any considerable illumination of the field. The angle would seem to be larger and the distance somewhat smaller than that given in the *Star Guide;* but it is evident that all the elements hitherto obtained are more or less unsatisfactory; possibly, however, the orbit (like that of 70 Ophiuchi) may be disturbed. In making the measures, bright field illumination with red light has invariably been used (this giving the best result), and the highest power employed which the night would bear; but since the end of November the air has almost always been unsteady, and good measures have consequently been difficult to obtain.

η CASSIOPEIÆ = Σ 60. MAGS. 4 – 8·3.

Epoch.	Pos. A.	Dist.	Wt.	Power.	Remarks.
1886·783	177°·5	4″·97	4	280	Definition fair
1886·909	178·1	4·69	4	200	
1886·944	177·1	4·69	4	280	
1886·980	179·0	4·45	2	200	Images unsteady
1886·991	179·2	4·85	4	350	Very good
1887·011	178·5	4·37	1	160	Images diffused and blazing
1887·063	180·03	4·65	3	280	Unsteady
1887·082	178·1	4·99	4	280	
1886·970	178·323	4·768			

With regard to τ Cygni (A.G.C. 13), since publishing the results of measures of this star (made in 1885) in the *Journal* of the Liverpool Astronomical Society, I have received a note of some measures made by Prof. C. A. Young at Princeton, New Jersey, with the 23in. refractor of that observatory, which differ so widely from my own as to lead to the inevitable conclusion that the object measured by me in 1885 must have been a spurious image. According to the Princeton measures, the angle in 1885 was about 70°; but there were several curious discrepancies in the various measures, for I find that the star was measured by Prof. A. Hall at Washington with the 26in. refractor on Sept. 25th, 1885, when he found P = 100·7° D – 0·62″—a result which, although differing considerably from my own, disagrees still more violently with the Princeton measure of about the same epoch. There is, however, but little doubt that the pair has since closed up out of reach of any but the largest aperture, and therefore the orbit computed by Mr. J. E. Gore (published in the *Ast. Nach.*), in which my measure was used, will require revision, as well as the data attached to the star in the *Star Guide* supplied by me to Mr. Sadler. The period in this case is evidently below 50 years, and it may turn out to be one of the shortest known; but the task of obtaining an orbit is one from which the most persevering computer might well shrink, taking into consideration the varying results obtained by two skilled observers, both using large refractors. **Kenneth J. Tarrant.**

Letchford House, Pinner, Feb. 9.

THE LUNAR RAY SYSTEMS—LIST OF STREAK SYSTEMS — ALPHA FORNACIS.

[26839.]—WITH reference to Mr. Gemmill's remarks as to these on p. 499, there seems to be less objection to dividing the individual rays, rather than the ray systems themselves, into the three classes of "Tychonic," "Copernican," and "Messier." Nevertheless, I think it will be found that there is no marked line of demarcation between the different classes, and it will often be found extremely difficult to decide into which division many of them should be placed, particularly, perhaps, in the two classes of "Copernican" and "Messier." The adoption of this method of classification will, though, indicate well the intimate connection existing between the "rays" properly so called and the ordinary light streaks. There are great numbers of these latter which present precisely the same appearance as the Messier rays in all respects, excepting, perhaps, length and brightness. The striking appearance of the "comet tail," as it has been termed, is, of course, due in great part to its surroundings; but the chief characteristics of the rays composing it, apart from their compound nature, appear to be:—(1) Straightness; (2) narrowness; (3) equable intensity; (4) uniformity of breadth; and these characteristics will also be found in very many of the ordinary light streaks. The two streaks forming the streak ζ in Plato, for instance, form, with the central crater, almost an exact miniature of the Messier system.

I had not overlooked Mr. Dennet's map of the Proclus system, which is a very useful one so far as it goes; but it does not give much information, if I recollect rightly, as to the characteristics of the individual rays, as regards differences in width, brightness, appearance, &c., or their connection, apparent or otherwise, with the numerous light spots and patches and other objects.

In the text to his "Charte der Gebirge des Mondes," Schmidt gives a list of 100 streak-systems, light-surrounded craters, and light spots. The following streak-systems extracted from this list will form an addition to those mentioned by Mr. Gemmill. Many of them are but insignificant, judging from the brief notes added by Schmidt. As Mr. Gemmill appears to be working in this direction, I hope he will observe some of these systems and make further additions to the list. A series of carefully-made observations upon some of the smaller ray systems with a map of the principal rays, after the style of that of the Proclus system made by Mr. Dennet, with notes on the class and characteristics of the separate streaks of the system would prove a real service, and that of some magnitude, not only to selenography, but also to selenology.

List of Streak-Systems.—Autolycus, Eudoxus A; Manilius; Menelaus; Taquet, east of Littrow (long. 92°W., lat. 21·5° N.); Tralles A; Cleomedes A; north wall of Mare Crisium (long. 57° W., lat. 22° N.; Taruntius; Dionysius, south of Apollonius (long. 62·5°W., lat. 2·2° N.); Timocharis; Geminus; north of Volta (Schmidt) = Chevallier in Neison; Gambart A; near Galilei (long. 58° E., lat. 8° N); Cavalerius (W. wall); Zuchius; Mersenius (W. wall); south of Sirsalis (long. 59° E., lat. 14° S.); Euclides; Alphonsus (S.S.E. wall); Lalande; Stevinus a; Furnerius A; Langrenus; Mädler; Timaeus A (long. 2° E., lat. 60° N.); Timaeus ——; Agrippa; Hipparchus d; Godin; Maurolycus.

In letter 26808, p. 520, Mr. Sadler refers to the suspected variability of the star α Fornacis, or 12 Eridani. In Mr. Gore's "Catalogue of Suspected Variable Stars" the authority given for the suspected variation is W. Herschel; and, in the *Phil. Trans.* for 1796, Herschel gives the observation "19, 12." If we assume, with Prof. Pickering, that the comma is equivalent to a difference of 0·2 mag., and take for 19 the mag. of the "Harvard Photometry," the magnitude of α, according to this observation, would be 4·4. The following, then, are the determinations by different observers of the magnitudes of these two stars:—

	H	U.N.	Heis.	U.A.	H.P.	Wms.
19 Erid.	(4·21)	4	4	4·5	4·21	4·0
12 „	(4·4)	3—4	3—4	3·6	3·77	4·1

It will thus be seen that there are rather strong reasons for suspecting variation in the light of 12 Erid. My observations were made on the 14th Oct., 1885, the comparison stars (δ and π Eridani) being the same for both stars. From Mr. Gore's Catalogue Lalande made it 3m., and Lacaille 3½. Are there any other determinations of the brightness of this star? **A. Stanley Williams.**

OCCULTATIONS IN MARCH AND APRIL, 1887.—THE TOTAL SOLAR ECLIPSE OF AUGUST 19.

[26840.]—BELOW I give a list of occultations visible in the British Isles in March and April of the present year, together with the elements for predicting them for any place where visible. The method for making the computation may be found in the ENGLISH MECHANIC, No. 1,075, for Oct. 30, 1875, and in subsequent numbers. I am pleased to say that this method has found favour in all parts of the world, beyond my most sanguine expectations. In a private letter received recently from Assistant-Astronomer Cooke, of the Adelaide Observatory, South Australia, he says: "You can easily understand that with our small staff, and the large amount of meteorological work we have always in hand, any regular series of occultation computations by any of the old methods would be quite beyond our powers. By your method, however, a whole month's visible occultations can be calculated in a very short space of time."

I shall send you at an early day the elements for predicting the total solar eclipse of 1887, Aug. 19. **Chas. L. Woodside.**

Boston, Mass., Feb. 1.

THE LUMINIFEROUS ETHER.

[26841.]—I SHOULD like just to say, with reference to a statement in letter 26791, that I was quite aware of Clerk-Maxwell's theory as to the phenomena of electricity and light being caused by movements of the same medium, and that I fully believe it to be correct. But this does not prove the medium to be "luminiferous ether" any more than the fact that two men are seen reeling about in similar fashion proves that they are both under the influence of beer, and not whisky. Many high authorities seem to consider that light, no less or more than electricity, is a movement of molecules of ordinary matter independent (to a certain extent) of their condition as constituting masses of what we call solids, liquids, and gases.

To take a rough illustration, a violin may be swung in the hand or carried about a room (mechanical motion): it may be played upon so that its molecules vibrate with that finer mechanical motion which causes phenomena of sound. It may be heated before a fire so that its molecules move in the manner required to produce the effects of heat. Its strings may be conveying electrical energy as motion of some kind; and all this variety of motions may be going on simultaneously in the ordinary molecules of the violin. Why may we not go one step farther, and suppose that these same molecules are capable of taking up and passing on that kind of motion which produces the phenomena of light? Why should an additional, non-material medium be required for this particular movement, which is not required for the rest?

Heat and light are in many respects closely related; radiant energy manifests itself as heat or light simply according to the surface it falls upon. Why should a supra-material medium be required for the one and not for the other? **A. X.**

[26842.]—IT appears that the various writers who have referred to my remarks upon this subject fail to apprehend my position in the matter. As I said before, it was not the luminous relations of the ether that I treated of at all, but the endeavours now being made to turn electricity into the ether.

Of course, as Mr. Grey says (p. 500), we know a great deal about the effects brought about by the agency of the ether; our knowledge of the undulatory theory of light is very considerable, and as trustworthy as any knowledge can be of matters which cannot be directly seen and measured. When I said that we know there is something which transmits light, and which we call the ether, and that is the end of our knowledge, I was obviously speaking of our knowledge of the actual nature of the ether itself—its *essence*, not of our knowledge of the effects produced by its agency. No one has yet touched the gist of my objections to the practice of making assertions as to the actual nature of a substance of which we really know nothing, and have no possible means of examination

No one has really ventured to defend the propriety of assuming the properties and nature of the ether, devoid of weight and friction, from those of matters possessed of weight and friction even in the state of gas of the utmost tenuity.

Mr. Grey, and also "E. L. G.," if I quite catch his meaning, object to my suggestion that it is just possible that the ether may be ordinary matter in the state which Crookes calls the fourth condition of matter, as found in ultra-vacua. But I merely expressed a hinted thought, springing from other thoughts not mentioned. It seems to me that we do not at all know what that fourth condition is; it is not at all inevitable that it is really "gaseous." When we pass beyond the bounds of knowledge and enter the realms of hypothesis, we are freed from many of the limitations of strict law. I can conceive readily that there is a limit of pressure at which "dissociation" takes place, just as there is a limit of temperature, and that matter may assume a condition wholly different from that in which we know it. Furthermore, I think that hypothesis is more reasonable and better formed than that which represents the ether as having the properties of a jelly or solid while not possessing the first fundamental attributes of matter at all. For it must be remembered that just as I said that we know nothing of the essential nature of the ether, so neither have we any knowledge whatever of the essential nature of matter or of energy or of force; in fact, the very fundamental property of matter, that by which we measure it—its mass or weight—is not a property of *matter* itself at all; it is a measure of *force*, which, for all we know, may be a something superadded to matter. It is an unproved, but reasonable and largely held, idea that matter as we know it, as the elements, is a manufactured article; that there is an unknown something underlying them, and into which they may be again resolved; that underlying, original element may very well be the ether, while the properties of ordinary matter may be derived from energy charged upon it.

In fact, it cannot be too thoroughly realised by every earnest thinker that, wide as may be our knowledge of actions in nature, we have absolutely no knowledge whatever about the real agents; of ultimate causes, the essence of things, we are utterly ignorant, nor is there the smallest probability that we ever shall know anything about them. It is well to recognise the limits of our field of operation.

I fully agree with Mr. Evans (p. 451) that we must assume ideal pictures of things beyond the scope of actual knowledge; in fact, our atoms and molecules of chemistry are really ideal pictures which embody certain known facts and derived theories; therefore I have no objection to the statement that the action of the ether in transmitting light can be represented by that of a jelly transmitting vibrations. But while that comparison (involving the giving it for a special purpose properties which we know it does not possess) may be convenient as aiding us to form an ideal picture of light traversing space, it is fatal to true knowledge to transfer the same idea to other conditions where we cannot with any truth bestow on it these artificial properties. As an instance, Sir W. Thomson, having originated this jelly notion, went on to indicate that a flash of lightning can be pictured as a crack in the jelly. Now, this is monstrous; we have no single particle of evidence that there is anything resembling electrical action in space; we have no knowledge of any electrical action excepting as related to ordinary matter; flashes of lightning occur only in the air, not in space; even the Aurora (which, however, is not an electric action, except in that all magnetism is electric action) occurs in the atmosphere. What right, then, has anyone to assert that electricity has anything to do with the ether when we are sure that no electricity is manifested where nothing but the ether is present?

That is the whole meaning of what I have said, that while we may form ideal pictures to aid us in understanding certain facts, we must not give actual existence to those pictures, or apply them to other facts of a different order. **Sigma.**

NOTES ON THE CHURCH ORGAN.—TO "C. R. O.," DEVON.

[26843.]—I HAVE read your remarks relating to the harmonic upper partial tones with considerable interest. I may commence my reply by remarking that, in the simple calculation of the vibrations of the harmonics, we have nothing to do with the "wolf." You must bear in mind that the numbers of the vibrations producing the upper partial tones are simply multiples of the number of vibrations of the prime. Thus, the first upper partial tone has twice the number of the vibrations of the prime: the second upper partial three times the number of the vibrations of the prime: the third upper partial four times the number of vibrations of the prime, and so on with unvarying regularity. If Helmholtz and Kœnig are correct, and the experiments of Seebeck, Cagniard-Latour, and other physicists go for anything, we must accept the above as conclusive. For your reference I give you the numbers of vibrations of all the notes which extend upwards from the C of 256 vibrations to the g^3 of 3072 vibrations per second, according to the just or untempered scale. It must be remembered that we have the just scale alone to deal with in considering the question of harmonic upper partials.

C	= 256	—Prime tone.
C sharp	= 266·66

d^3	= 2304	—8th upper partial tone.
d^3 sharp	= 2400	
e^3 flat	= 2457·60	
e^3	= 2560	—9th upper partial tone.
e^3 sharp	= 2666·66	
f^3 flat	= 2621·44	
f^3	= 2730·66	—10th upper partial tone.
f^3 sharp	= 2844·44	(= 2816 vibrations).
g^3 flat	= 2949·12	
g^3	= 3072	—11th upper partial tone.

With the above scale before you, perhaps you may more correctly or more easily judge your own way of thinking, as set forth in your letter (26797). I shall be in your town for a few days shortly, and it will afford me much pleasure to have some conversation with you. Will you let me hear from you direct. **G. A. Audsley.**

Devon Nook, Chiswick, W.

[26844.]—I NOTICE that Mr. Audsley in his last article but one on "The Church Organ" intimates his intention of directing attention to Mr. T. Casson's system of organ construction. Having made myself well acquainted with it, and believing, as I do, that it is destined to work a revolution in the great art of organ building, I am sure Mr. Audsley will forgive me for suggesting to him that his account should be as exhaustive as possible, and thus aid in bringing to the front a system as excellent as it is simple.

E. W. Taylor, Mus.D., F.C.O.

HORIZONTAL WINDMILLS.

[26845.]—I THINK it is only right to mention, upon reading what "Q. E. D." says in letter 26823, p. 522, that I haven't had practical experience in the construction of any class of large windmills. Now, as to the merits of any form of horizontal windmill, it may interest some of "ours" to know that this is an ancient invention. I believe that I was experimenting, say, some fifty years ago with an arrangement for feathering the sails by means of a fixed eccentric similar to that in use upon feathering paddle wheels. As to the diagram of F. Russell, upon p. 522, if three of those sails were removed, I am convinced that it wouldn't revolve, and certainly it couldn't if it had any work to do, whereas even one of these sails upon a vertical would work well. To "Q. E. D.," same page: I really cannot see any reason to suppose that any vertical windmill would require a stronger framing or tower to carry same than would be necessary for a horizontal of same power. I am of opinion that the latter would offer more surface of resistance to the wind than the former—most of us know how, when a sail-boat is "put about" in a strong breeze, how she "lays over" until "way" is got upon her, and then assumes a more upright condition.

I cannot see any reason for assuming that the more or less jerky banging sails, as these proposed with ropes and stops, wouldn't, in a gale, require a much stronger edifice, if erected at a reasonable elevation. **A.**, Liverpool.

WIND POWER.

[26846.]—AS there appears to have been some slight difference in opinion among some of your correspondents relative to the pressure of wind, I send you a table which may be of some service to our friends contemplating the use of wind power.

This table is calculated from the data of Col. Sir H. James, and appears in his "Meteorological Observations," published by order of the Secretary of State for War, 1860.

Velocity and Pressure of Wind.—The pressure varies as the square of the velocity, or $P \propto V^2$. The square of the velocity in miles per hour multiplied by ·005 gives the pressure in pounds per square foot, or $V^2 \times \cdot005 = P$; also the square-root of 200 times the pressure equals the velocity, or $\sqrt{200 \times P} = V$. The subjoined table is calculated from this data.

TABLE OF VELOCITY AND POWER OF WIND.

Pressure in lb. per sq. ft.	Velocity in miles per hour.	Pressure in lb. per sq. ft.	Velocity in miles per hour.	Pressure in lb. per sq. ft.	Velocity in miles per hour.	Pressure in lb. per sq. ft.	Velocity in miles per hour.

Lance Corporal
(2nd L. N. Lancashire Regiment).
Pembroke Dock.

[26847.]—I FIND that at Liverpool Observatory, Bidston Hill, which is about 200ft. above mean sea level, the mean hourly speed of the wind was in—

1879	15·6 miles per hour
1880	15·5 " "
1881	16·8 " "
1882	18·0 " "
1883	17·4 " "

At Oxford (113ft. elevation, I believe), Mr. Baxendell informs me that he has ascertained the

hourly mean for six years was $10\frac{1}{2}$ miles, and at Greenwich, where the anemometer is "50ft. above ground," the mean for 13 years is 11·9 miles. These results are much more favourable in regard to speed than at Southport. It is certain that much depends on elevation and situation. Bidston Hill is, of course, exceptionally situated, and it is not surprising that a high wind-speed is shown there. I hope the discussion will tend to some practical result.

Southport. **Benjamin Boothroyd.**

[26848.]—F. RUSSELL'S plan (letter 26821) would knock itself to pieces; I understand it to be four flaps to open and shut, according as the wind blows. Fancy the jarring of the flaps opening and shutting. F. Russell has left much to imagination, and does not appear to have thought of springs to mitigate the jarring. **R. S. T.**

HORIZONTAL WINDMILLS.

[26849.]—I CONTINUE to read with much interest the ingenious contributions of your inventive correspondents on the practicability of horizontal wind motors, but I have seen nothing yet that impresses one with the conviction of success. Mr. Hoskens (p. 522, Feb. 11) seems nearest the mark; but when he gets out of his model period into that of utility he will meet with many difficulties which do not appear to present themselves to his mind as yet, and which will probably render his machine unacceptable. I see he has adopted my suggestion of extending his outer spar as much below as above the arm to which it is fastened; but I qualified my opinion of it, and fear he will find it bristle with inconveniences in practice. Then his 11in. planks of 10ft. long will abstract a good deal of his sail-power, driving against the wind, when, to use a nautical idiom "you can hardly hold the edge of a knife to it."

A Mr. J. T. Hewes appears to have applied for a patent (No. 2154) on this plan in 1864; but it does not appear that he ever completed his specification.

The device so modestly introduced by Mr. F. Russell, of Walsall, is liable to much the same objections. The slamming of those doors of his, as each changes its position from going before the wind to coming upon it, requires so strong a framework that it is a mere variety of Mr. Valance's system, and would be very lumbersome, and any cordage to check the flam out of the sail (or door) would be liable to chafe itself through very soon. Jibing in a boat or ship running before the wind takes place at long intervals, and is carefully attended to by those on board, who haul in the sheet, and ease it off again. But in a horizontal wind-motor on either of these plans, let us say (in a working machine) at only eight revolutions a minute, every sail must jibe eight times in that brief space, or 480 times in an hour, automatically, or without extraneous aid. I do not say that this is a fatal objection; but no remedy has yet, I believe, been discovered for it.

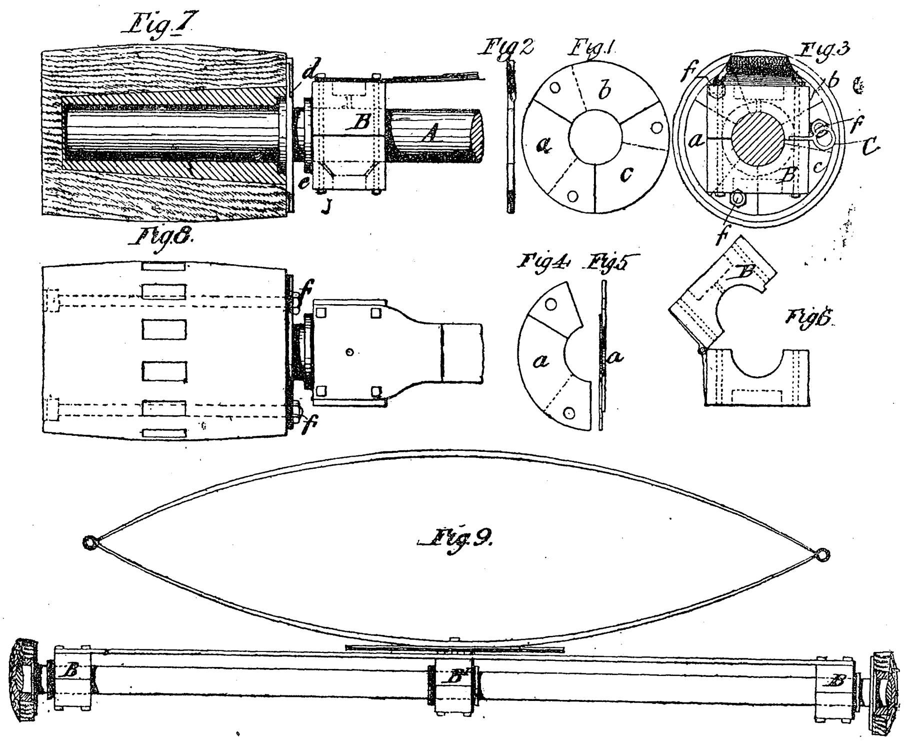
The suggestion of "Q. E. D." on the same page, to follow the lead of the ingenious Saml. Miller with more modern improvements, may be the right clue. But "Q. E. D." makes a mistake when he says that such a horizontal wind-motor "would need no more support than the absolute power given out by the machine at its best." He seems to have overlooked the resistance offered by the arms and flattened sails on the reverse side, for which at least 25 per cent. should be added. The support to a wind-motor capable of 2H.P. should be computed to bear a strain of at least 3H.P. I join with your other readers in offering thanks to Mr. Boothroyd (26760) for his lucid explanations and his table of wind velocity at Southport.

London, 12th Feby. **Raymond Browne.**

IMPROVEMENTS IN CARRIAGE WHEELS.

[26850.]—MR. EDWARD M. EARLE, of Kingston, Jamaica, has recently protected some improvements relating to carriage wheels and axles. He provides a very easy method for attaching wheels to mail-coach axles applied to carriages, buggies, and other vehicles by making the flanges in, say, three pieces, *a b c*, Figs. 1, 2, 3, 4, and 5, which partly overlap, and are flush with each other, with holes to receive the nave-bolts *f f f* when they are put over the axle A between the two shoulders *d* and *e*, and secured to the wheel by the nave-bolts *f f f*, holding the wheel on the axle as firmly as the ordinary solid flange, with the advantages, however, that when worn out, they may be replaced at a trifling cost without interfering in any way with the shoulders *d* and *e* on the axle. They may be taken off and replaced by any one who can use a spanner, and no smith is required.

Combined with these flanges or not, Mr. Earle makes the axles A of ordinary carriages, buggies, or other vehicles straight and round, with one or two shoulders near each end, as shown in Figs. 7, 8, and 9. The wheels revolve on the axles A, and the axles in bearings B; thus a very free or double



rotary motion is produced when the vehicle is in motion. The extra shoulders on the new axle are placed at particular points to keep the box-bearings B in place. Or, instead of using the means before described for securing the wheels in their places, the ordinary screw-caps may be used. The centre-box bearing B^1 on the front axle, as shown in Fig. 9, will have the perch attached by a coupling somewhat similar to that shown with reference to C, Fig. 3, which is for connecting the shafts or swingle-tree gear. The hind axle may be secured to the perch by stays.

77, Chancery-lane. **Jensen and Son.**

CLOCK AND SUNDIAL.

[26851.]—THE problem that Fred. Carre ascribes to me (p. 521, 26818) was not, I think, to make an identical dial give clock time throughout the year, but for a kind of double dial, with two gnomons and scales, each to serve that purpose nearly half the year. If I at first thought of their serving jointly through the whole year, I afterwards gave up as impracticable about the last half of December and a week in June. With those two exceptions—viz., about the week that the sun is in northernmost declination and the fortnight that he is southernmost, my form of dial (universal for all latitudes by standing on a pedestal rightly inclined), would, by mere inspection, give very nearly the second of mean time (certainly the tenth of a minute) whenever shone on by a sun 10° above the horizon. A sun lower than that is too refracted to give this degree of accuracy on any dial, at least outside the Tropics. Near the Equator we might so modify the scale of minutes as to obviate refraction, but not in moderate latitudes. I will shortly send the form of dial.

E. L. G.

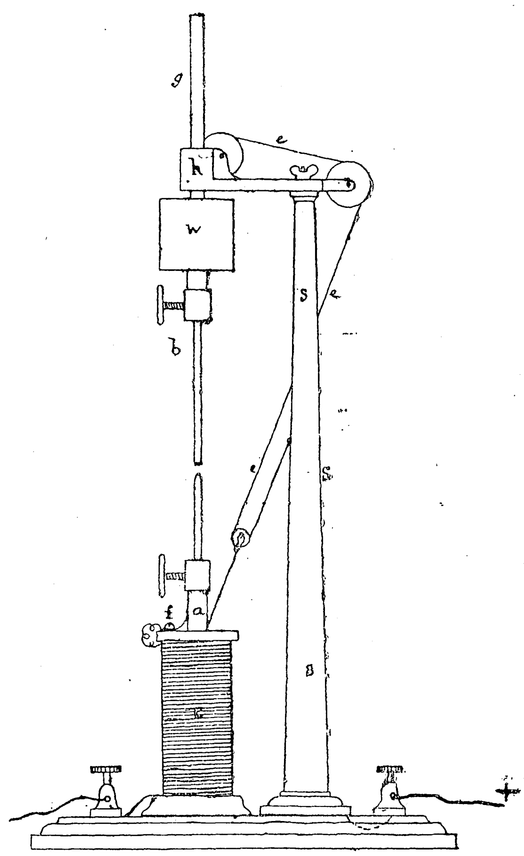
ROAD REFORM.

[26852.]—I THINK "F. R. A. S." must be looking at the work of reforming our roads with a microscopic eye. If taking traffic over unnecessary hills and dales is cheapest, why did our railway companies cut their roads level? Not because steam engines could not ascend gradients, but because it was cheaper to remove the hill-tops once for all, rather than carry a thousand times the weight of the hill-tops in traffic over the entire hills.

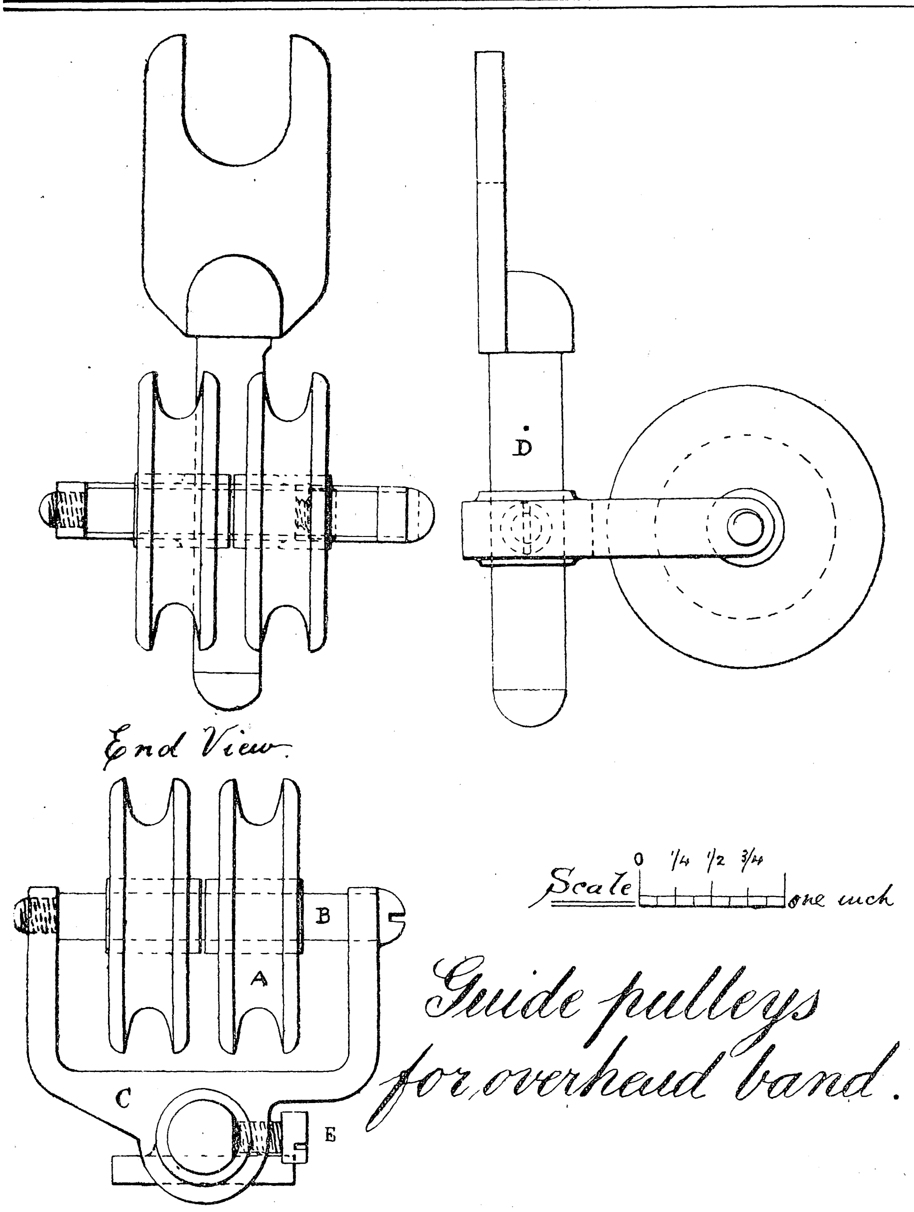
In reforming our roads, probably one half, at least, of our road hills might be avoided without materially hurting private property or increasing distance. The roads to be first reformed should be those upon which there is most traffic. The foot-pound unit cannot be discarded in calculating physical labour, for if "F. R. A. S." were to take one of the hill-tops to remove into a valley below, he would first go and measure the amount of earth to be removed before he would tender for the job; hence, he asks me questions respecting the roads of Devon and Cornwall which no man can approximately answer. A road-hill may be thick or thin, a valley wide or narrow, and the quantity to be taken from a hill will probably depend upon the valley to be filled up. A road-hill from which 20,000 cubic yards of earth had to be tippled into a valley below would probably cost an outlay of £600 with ordinary workmen; but if I had an imperial prerogative in the matter, I should have more than a hope to see it done for half that money. **Norfolk.**

A SIMPLE ARC LAMP.

[26853.]—THINKING it might interest some of your numerous readers, I venture to inclose a sketch of a simply-constructed arc lamp which I



have designed and believe to be original. Referring to sketch—*a* is a brass tube with a holder for the negative carbon. At the lower end of this tube a short bar of soft iron is fixed, and the whole is capable of vertical motion in the helix *c*. A light spring (*f*) makes connection with *a*, and is again connected to one end of coil, the other going to the negative terminal. *g* is a square guide-bar sliding in guide (*h*) and carrying the holder and upper carbon, *b*. It has a groove down one side in which the supporting cord (*e*) may run. *w* is a



weight counterbalancing that of *a*, to which it is connected (not electrically) by means of the cord and pulley arrangement. It is sufficiently heavy to bring the two carbons together when no current is flowing. To effect this, taking into consideration the mechanical advantage of the pulley arrangement, the weight of *w*, together with that of holder, should be rather more than half that of *a*, and should be made adjustable, so that the length of arc may be regulated to suit the current employed. The action of the pulleys and cord is apparent. Through whatever distance *a* ascends, *b* descends through double that distance, and thus as *b* is the positive carbon and burns at twice the rate of *a*, the centre of light will remain practically stationary. The whole action of the lamp is simple. A current entering at + terminal flows up the support (S), down through the carbons, round the coil, and back to the source. The carbons are immediately separated by the pulling force exerted by the helix. Should the separation exceed a certain amount, the weight (*w*) brings them together again.

Sydney, N.S.W. **H. D. B.**

LATHE MATTERS—GUIDE PULLEYS FOR OVER-HEAD BAND.

[26854.]—FREQUENTLY, while working with the overhead motion as supplied by the maker of my lathe, I have been troubled by the band overrunning the pulley of the drilling spindle or other tool in use at the time.

When this occurs during a finishing cut, it leaves an objectionable mark on what would otherwise have been a finished surface. A very slight amount of guidance is all that is necessary to prevent accidents of this kind, and, in the hope that it may be of use to others in the same position as I used to be, I send the accompanying sketch of the guide pulleys which I now use with perfect success.

When in use, the forked tongue is fixed under the nut of the central bolt of the Willis pattern tool-holder.

The pulleys on their movable framework (C) are then moved along the arm (D), until the band runs nicely on to the pulley of the drilling spindle, and is then clamped into position by the set-screw (E) at the side of the frame.

The pulleys I prefer made in hard wood, thickly bushed with brass, as these bushes can be easily renewed when the pulleys become noisy through wear. They run upon a steel spindle (B), one end of which is screwed into the gun-metal sliding-frame (C).

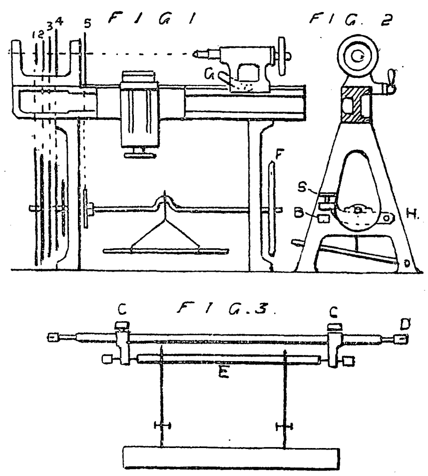
The arm (D) and the tongue are of gunmetal in one piece, and though shown forked for fitting round the bolt of a Willis tool-holder, it could be easily fixed by a couple of set-screws in any convenient position.

Castings of the gunmetal parts off my patterns may be obtained at Messrs. Mills's foundry, whose address I have already given in the address column. **W. R. W.**

[26855.]—To Mr. Carre, who asks me to return a drawing he sent me, I am very sorry to have to confess that I fear it is lost.

I am glad "Vulcan" is working at the "E. M." lathe. The primary idea with which we started on the "front-slide" railway was that the saddle should pass out of the way without requiring the poppet to be disturbed, nor work held between the centres unfixed; possibly, we may be sacrificing too much to obtain this, but, for my part, I do not feel able to give it up and go back to the old system of lifting the poppet about. In a properly-arranged lathe the washer under the poppet will turn a quarter round, and lift out between the shears as easily and quickly as in "Vulcan's" plan, but we don't want to have to lift it at all.

As to the lower part of the lathe, I send a little sketch to show what seems to me a good way of arranging matters. I think it would be a great convenience to have the flywheel *overhung*, because then the belt for speeds 1, 2, 3, 4, and for the overhead need not have hooks and eyes, but might be spliced or endless, and have no nasty periodical jerk when going over a small pulley; the belt on speed 5, which represents the groove in the large faceplate, works with a small separate pulley *inside* the frame; it will be a shorter belt, and will require a hook and eye. The bed is really *better* supported on the moved-in frames; also the crank shaft is shortened, and therefore not so liable to spring. Instead of centres the crank-shaft runs in a cast-iron bearing, separate from the frame but hinged to it at H, Fig. 2; a screw, S, in the other end of the bearing-arm rests on a lug B, and takes the weight of wheel, axle, treading, &c. This screw and the one at the other end is easily adjusted by



hand, and serves to tighten or loosen the band. The rocking end of treadle has also a height adjustment, which will compensate for that of the shaft, see Fig. 3, where D is a strong stay-bar (very different from the little ⅜in. rod usually put in) CC, are short cranks fixed upon it, and carrying the points on which the treadle bar E turns. This part is similar to Mr. Plant's arrangement; at *k k* the bottom of the forked pitman ends take hold, on Mr. Evans's plan, so as to support both ends of the treadle foot-board.

How do our friends dislike this arrangement?

I have four ostrich eggs to mount, and am rather disturbed to find the small end is about as large as the other; also they are not truly circular, but slightly flattened, elliptical in cross-section slightly, and elliptical (not oval) in longitudinal section, too, yet not truly so. Surely the bird's lathe was out of order. Will someone advise me? I will give my experience if anyone cares for it.

F. A. M.

GUT LATHE BANDS SUPERSEDED.

[26856.]—I HAVE resided for some years in the dampest of our English counties, and have been worried by the continual stretch and softening of "gut bands" in my foot lathe; I am now happy to say I have discovered a most satisfactory substitute in the "Metallic Sash Cord," warranted by the patentee to last 150 years!

I anticipated objectionable results in heat and friction; but was agreeably surprised to find that the cord remains as cool as possible under the highest rate of speed, and that there is no abrasion in either that or the wheel. I prefer brass or copper hooks and eyes, as they easily admit of soldering to the cord; but in my case, having a lot of the above steel joints on my hands, I have been content to fasten them in the following way:—I have drilled a very small hole through the screw part of each by softening them, and have attached them to the cord with "bicycle cement," then putting a sharp steel pin through the holes. This additional trouble is quite unnecessary when the work is soldered in the manner described. The metallic cord should be thoroughly stretched and straightened before mounted with hooks and eyes.

Eos.

THE STRUCTURE OF EUPODISCUS ARGUS.

[26857.]—MR. E. M. NELSON, in the April number of the *Journal* of the Royal Microscopical Society, describes the above diatom as "consisting of two membranes; the outer with oval areolations with granulated interspaces, and the inner with white dots with very minute perforations grouped around them."

With regard to the outer membrane I have nothing to say, as it entirely agrees with my own observation; but with all due deference to so great an authority, I cannot accept his interpretation of the inner membrane.

I admit the white dots; but in my opinion they are perforations of the same character as the outer

only smaller, and what he considers minute perforations to be granulations also, but larger than those on the interspaces of the outer membrane. I am confirmed in this opinion by the fact that there are similar dots scattered about in the interspaces of the outer membrane, which behave when viewed either in or out of focus in precisely the same manner, showing no colour, while the minute granulations change from red when in, to white when out of focus, the same as Angulatum.

T. F. S.

RAILWAY SIGNALS.

[26858.]—MR. STRETTON says that "signalmen sometimes omit to put back the signal lever," consequently the signal is left in the "off" position, and the train unprotected—which certainly is correct, having led to many serious and fatal accidents. Now, the object of my patent apparatus is for the train to automatically release the signal to "danger," without interfering with the duties of the signalman; and should the lever be left "off," the signal would be at "danger," the lever (by means of a catch) might admit of being put back in locking position, thus preventing the signal being locked by electricity on the wrong side.

Jno. Harrison.

185, Well-street, Hackney, E.

ELECTRIC LOCKING FOR RAILWAY SIGNALS.

[26859.]—I HAVE read with very great care and interest Mr. Spagnoletti's description of his system of electric locking (page 521, letter 26184), but the important point which I raised in my former letter, page 436, 26710, still remains absolutely unanswered, and cannot be explained away.

Mr. Spagnoletti says, page 521, line 28, "On 'A.' putting the lever back it is mechanically locked." This is perfectly true; but suppose for a moment that signalman "A." omits to put the lever back. What is the result? Simply, the electric locking system will be rendered useless, and fail in its object.

No system can be considered safe which depends solely upon one man replacing his lever. I am very glad to learn that Mr. Spagnoletti (p. 521) has "somewhat altered his views, and prefers two strings to his bow." That opinion entirely coincides with my own, and for that purpose I would give the signalman at each end of each block-section the control over the starting signal at the entrance to such section. For short sections the mechanical slot-signal is very efficient, and for long distances I know of no appliance more simple or more efficient and safe than the "electric-slot."

Mr. Spagnoletti considers that the important objections to the lever having to be put back are "quibbles"; but he must remember that it is upon such so-called quibbles that railway signalmen are, and have been, sent to prison for six months' hard labour; therefore, I cannot consistently with my duty report in favour of any system which does not provide an absolute mechanical block-system which cannot fail in its object, or break down by the mistake of one man.

Clement E. Stretton,
Consulting Engineer, Amalgamated Society of Railway Servants.

St. Pancras Hotel, London, N., Feb. 11.

[26860.]—I WAS very pleased to see Mr. Spagnoletti's account of his system. Would it be asking too much to give a sketch of the lock with the electrical apparatus for releasing it? One or two points are, however, not quite clear to me. I do not see how it is possible for one instrument at a junction to work any number of lines approaching it. Also, at what time is the disc "Train arrived" taken off in the indicator?

Reymond.

FAST TRAINS.

[26861.]—I CAN assure "M. R." that I carefully timed the train referred to in my letter (26774), between Luton and St. Alban's, and it was done in as near as possible 8 minutes.

O. H. P. Scourfield.

VERY DAMP.

[26862.]—IN the early part of 1872 "E. L. G." had a discussion with "Sigma" concerning a miraculous comet, which the former contended had caused the Noachian Deluge; and *apropos* to letter 26832 I wish to say that I have no desire to renew that controversy. If it pleases my friend to imagine that on one occasion six hundred feet of rain fell in a single day, it is not for me to argue about the matter—in fact, *argument* is impossible. I may mention, however, that at present the wettest place in the world has a rainfall of only six hundred inches in a *year*. A fall of one inch in twenty-four hours is not common, and a fall of six hundred feet in that time is nonsense. I can easily understand how a man who manages to believe this rejects the evolution theory, and personally I am glad he does reject it.

Wm. John Grey, F.C.S.

Newcastle-on-Tyne.

THE ACHROMATISM OF LENSES.

[26863.]—IN reply to "W. G. P." (letter 26795), the formula I gave is certainly not a new one. I cannot say to whom it is due; but my first meeting with it was in Barlow's paper on "The Object Glass," where he uses it to find the dispersive ratio of a crown and flint glass pair. Anyhow, it can easily be deduced from ordinary optical equations; but I consider it quite unnecessary to take up space with a demonstration. I have an impression that Sir John Herschel also used this formula. As regards the modification for a particular value of *s*, which has relation to the Galilean form of opera or field-glass, I believe Dr. Brewster used it in discussing the prospective improvement, or increase, in magnifying power, without destroying achromatism, by the use of eyeglasses of high dispersive power.

I am not so readily convinced that the formula given by your esteemed correspondent is "much more correct" than the preceding one. It seems to me to be purely an eyepiece formula—that is to say, the emergent rays of different colours are to be rendered parallel; whereas in the original formula, which is, in its unmodified form, strictly an objective one, the different coloured rays are to be brought as nearly as possible to one focal point. I freely admit that in its modified form it may not be altogether correct, owing to the altered conditions, as the rays are then transmitted direct through the concave lens to the eye, and are not brought to a focus; but if the original formula is used, and the rays permitted to come to a focus, I see no reason for doubting the correctness of the equation.

I should be glad if "W. G. P." and "F.R.A.S." would notice the following matter. Recenty, in looking carefully through Prof. Harkness's "Theory of Achromatic Object-glasses," in which he uses Cauchy's formula, it occurred to me to compute the constants for several of the new optical glasses. But I could come to no satisfactory conclusion, as to which lines could be considered to give the most nearly correct constants. If the formula were strictly correct, any three lines should give identical results; but I do not find this to be so. If, then, we have, say, a table of measured indices for the lines A to H inclusive, which three should be used to compute the constants, and what is the most correct method of computing them? Dr. Hastings speaks of using the "method of least squares" for a similar purpose; but no example is given.

Prof. Langley, in his "Observations on Invisible Heat Spectra," speaks of the use of Wüllner's new formula (founded on Helmholtz's theory). Can any of your correspondents say what this new formula is, and in what respect it differs from Cauchy's? Reference is made in the Professor's pamphlet to Wiedemann's *Annalen*, Band XXXIII. p. 307.

Orderic Vital.

WASTE IN LECLANCHE BATTERIES.

[26864.]—PERHAPS it may interest some of the readers of "Ours" to know a simple and inexpensive method of preventing the creeping salts in Leclanché batteries. I have used the following for some time with perfect success. After charging the battery with the exciting solution, pour carefully a layer of oil (I use raw linseed oil), about $\frac{1}{2}$in. thick, on the top of the solution, where by its lighter gravity it remains and effectually prevents creeping salts.

J. A. Halhead.

BURNT AIR.

[26865.]—THE inconsistency of human nature is truly marvellous. Here we have "A. P. S." rebuking me with scathing irony for writing what he avers I do not know, whilst he himself concludes his diatribe with a merely weak-kneed hypothesis. As to what is, or what is not, an absurdity, I don't think the world at present is prepared to accept "A. P. S.'s" *ipse dixit*. At all events, when a man deliberately calls a thing an absurdity, the onus of proving it so rests with him.

In corroboration of the aqueous vapour theory as set forth in my letter (26792), I beg to refer "A. P. S.," or any other sceptic, to the "Encyclopædia Metropolitana," 1840 edition, article "Stove," and if this is a manifest absurdity, I will ask "A. P. S." to explain the following, which occurred within my own experience. Two boilers recently under my charge, of the cylindrical multitubular marine type, connected through their smoke-boxes and dry uptakes to one funnel, in such a manner that a small segment of each boiler shell was inclosed within the uptake, and subject, of course, to the heat of uptake. These portions of boiler shell were in the steam space. A process of rapid deterioration by oxidation took place within the boilers on these heat exposed surfaces only, purely local, and not in any sense allied to boiler corrosion, as generally understood to be due to magnetic action. Both boilers are fitted with Hannay's patent "Electrogen," which acted admirably, for there is no sign of deterioration in any other part.

How will "A. P. S." explain this but on the hypothesis that the immediate layers of steam, in contact with these heated portions of the shells, are decomposed, and the free oxygen thereon combining with the iron? The ends of the longitudinal stays in this vicinity are similarly affected, $2\frac{1}{2}$in. stays being quickly reduced to $2\frac{1}{8}$in.; but bear in mind only in the locality particularised. And let me say that the heat here never approaches to a red heat; flame there is none—merely the hot products of combustion, so that the analogy to a hot stove or stove pipe is nearly perfect.

I cannot think the red hot gun-barrel is a *sine quâ non* to the decomposition of aqueous vapour.

J. Q. D.

GELATINE HYGROMETER.

[26866.]—ON reading your article on p. 426, I made a gelatine hygrometer as per sketch, Figs. 1 and 1a, but with six instead of three free coils. This I fancy too sensitive, and reduced the number of coils to three. They are made by varnishing one side of a paper strip $\frac{7}{8}$in. wide with a varnish I had by me, consisting, I believe, of shellac and a little gum benzoin. The varnish being about the consistency of French polish, it took three coats to produce a shiny surface.

While still damp, I coiled the paper round a $\frac{5}{8}$in. ruler, and left it till the outside felt dry. I then slipped the ruler out, and allowed the inside to dry,

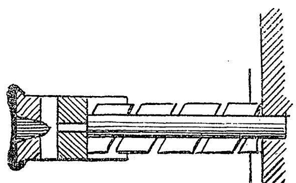


FIG 1a.

FIG. 2.

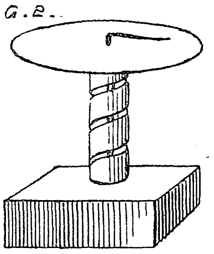

FIG. 1

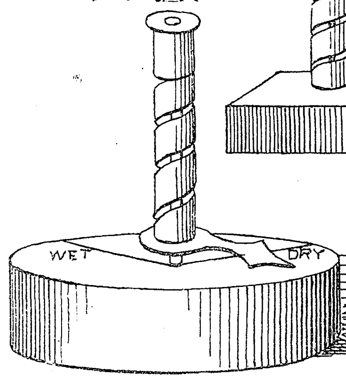


and then replaced the coils on the ruler, coiling them tightly, and fixed the ends with indiarubber bands.

Not knowing the proper proportions, I soaked some gelatine (Nelson's opaque) in a half-saturated solution of salicylic acid (which was hot) until I had a glue of the thickness of treacle. With this I gave the paper two coats, and left to dry. Before quite dry I again loosened the ruler, and separated those coils which had stuck together. I then replaced the ruler and indiarubber rings and left till next day. The coating of gelatine when dry was about twice as thick as the coloured gelatine on crackers; I used cartridge paper. A wooden rod was then fastened with shellac to the top of a cardboard box, and a cork made to fit the top of it.

This cork I drove into an empty Eley cartridge case, to which also one end of the coils was cemented; the other end hung freely, and carried a paper index. In Fig. 2 the wire index is stationary, and the dial revolves with the paper.

Glatton.

DEPOSITION OF ALUMINIUM.

[26867.]—IT would be of interest if Mr. White (p. 521) would give details of Mr. Thompson's pro-

cess of depositing aluminium, for very little seems to be known about it, and Gore, quoting from the *Chemical News*, XXIV. 194, says the temperature was "about 500° Fahr." Perhaps Mr. White would tell us how the "strip" referred to was coated with aluminium. A. J. T.

REPLIES TO QUERIES.

*** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[61048.]—**Electric Conductors.**—The printer, in adding a dot after "in." in my question (2), page 502, has answered it. For want of this dot under Mr. Lancaster's table, page 457, I failed to understand that he meant the current per square *inch* of conductors is 1,400 to 1,700, which this little dot has enabled me to do. In looking further into Mr. Lancaster's table, I now consider that 19/16 means only one wire, each way, of 19 and 16 gauge for forward and return current respectively. —ACIER.

[61083.]—**Axles Breaking (U.Q.)**—TO MR. RABACHE.—When once a flaw in steel has started, and the jar or work is continued, nothing can stop its growing. It is easy to speak of making things "unbreakable"; but I ask, Can it be done? I reply, No.—PRACTICAL RY. MAN.

[61084.]—**Fireclay.**—I observe with pleasure that I have not received the castigation which perhaps I deserved. What do your readers say to a lining for a furnace made of—ganister (nearly pure silica), alumina, lime (milk of), as a binder, and magnesia? For the moment, leave cost out of the question.—R. S. T.

[61138.]—**Yacht Steering.**—Mr. Beeching will find my address advertised. I think "H. S." may modify his opinion when he is informed that the yacht in question would be shallow, and intended chiefly for river sailing, in which quick turning is essential.—G. H. V.

[61338.]—**Coiling Wire.**—Suppose this querist uses a built-up mandrel for winding the wire round, and, having hammered or rubbed the latter into proper position, drives out the centre or tightening-piece of his mandrel, will not that suit him? Probably he disarranges his coils in forcing the wire off the mandrel. The remedy is to take the mandrel out of the coils by withdrawing a centre-piece.—NUN. DOR.

[61340.]—**Gramme Dynamo.**—Should not this querist adopt some one of the series of measurements given many times in back volumes? It seems to me that particulars of all sorts of small dynamos have been supplied over and over again. C. K. L.

[61350.]—**Air-Gun.**—To answer this query it would be necessary to examine the gun; but let the querist refer to p. 43, this volume, and p. 36, last volume, and he will probably be able to understand the construction of his gun.—C. K. L.

[61452.]—**Electrical Apparatus.**—Secondary batteries can be charged by means of a primary battery for lighting to advantage. There being but few cells used, and the solution can be worked out almost to complete exhaustion, which is impossible when lighting direct from primary batteries on account of the fall of E.M.F. The secondary batteries are charged in parallel from a set of three to four primary cells (in series). The secondary batteries are connected to a switch for turning them into series and on to the lamp circuit, or in parallel on to battery circuit. The following formulæ and example may be useful:—
Let

P = average candle-power required,
h = number of hours lighting per day,
$24 - h$ = available charging hours.
C = minimum charging current which for $(24 - h)$ hours would give Ph, the candle-power hours required.
V = E.M.F. of each secondary cell.

Supposing charging from primary cells takes place the whole of the time when lamps are not on—that is, for $(24 - h)$ hours, then

$$C = \frac{P \times h \times 4}{V\,(24 - h)} \text{ allowing 4 watts per candle.}$$

Example.—Let

P = 15 (three lamps of 5c.p. each),
h = 4
V = 2

$$C = \frac{15 \times 4 \times 4}{2\,(24 - 4)} = 6.$$

Thus six ampères for 20 hours charging accumulators in quantity would give 60c.p. hours. In my formulæ I take 4 watts per candle, which I find sufficient for loss in secondary batteries, assuming the lamps have an efficiency of 3 watts per candle. —W. HABGOOD.

[61466.]—**Gold Gilding.**—The answer to this in issue of January 28 may, in the hands of your correspondent, be successful, but is hardly a usual one. The common way is this: To begin with, most metals will do if clean without painting, but are generally better for several coats. The last should dry flat. Wood or any absorbent material must be painted, or something done to prevent the gold size drying in too rapidly. It will generally be best to give the parts to be gilt, whether painted or not, a thin coat of shellac varnish; it makes the surface smooth, and prevents the drying in. Next, the parts to be gilt are coated with gold size (mentioned again below), and when it is just tacky to the back of the finger the gold is laid on, either directly out of the book or preferably with a tip or thin, wide, long-haired brush, out of a pad generally made of soft leather, with a back of parchment to keep the gold in. The gold is taken up by the knife and manipulated till in a suitable position on the pad, and then gently blown down flat. Seeing this done would be advisable, or you will spoil plenty of gold. It is then cut with the knife, which must have a smooth, sharp edge, into suitable pieces; for some things they do not want cutting at all, but it is very difficult to lay a whole leaf at once. It is then taken up by the tip, which is generally rubbed on the hair or beard, but unless this is charged with some *statical electricity* in the shape of hair-oil, it will not assist the tip to lift the gold. When the gold is in place, it is pressed lightly on with a bit of wool or a soft-haired brush, and left for a time, and afterwards brushed off with a somewhat harder one. Gold size.—There are two kinds used commonly, one known as quick size, which dries under an hour, and is, therefore, only suited for small or short jobs, though it may be slowed by mixing chrome yellow in tube with it or a little oil size. Oil size is sold in pots, is something of the consistency of white lead, and requires thinning with quick size, and sometimes drying oil, before use. It requires some experience to do this, so an amateur had better use quick size, though the other makes the best work. There are other kinds made, but cannot always be had, and not in small quantities.—J. M'G.

[61474.]—**Silver Cell.**—Whatever does your correspondent, "C. D. R.," mean by "previous to connecting up (chloride or silver cell) just short circuit for ten minutes"? I have made and used a number of these cells, and have always found that a cell short-circuited for even ten minutes was half spoilt. Short-circuiting battery cells means simply wasting their contents.—J. PEYTON DAVIES.

[61504.]—**Double Electric Bells.**—Thanks to Mr. Lewis for his reply. Should he or any of our readers wish to know more about the short-circuit bell he is good enough to send a sketch of, they can do so by referring to pages 572, 596, and 646 of Vol. XXI. "E. M." At the time this bell was introduced (1875) for some reason it met with considerable opposition; in fact, from my own point of view, faults were found that did not in reality exist. I had one of the bells made exactly as Moseley's, and testing it with same cells as the ordinary one, its sound was quite equal, if not louder. This idea is evidently entertained by the writer of the articles in the *Electrician* for May 14, 1886, for he states: "Bells arranged in this manner, however, do not ring so energetically as ordinary trembling bells with a corresponding amount of battery power." I do not quite understand what you mean by expecting to find a spark at the contact breaker (or rather maker); the circuit is not actually broken, is it? For Moseley's improvement on his first bell, see *Electrician*, p. 152, Dec. 24, 1886; in this he places the contact maker between the magnet coils, in the centre of the armature.—M.M.I.SC.S.

[61506.]—**Compound Engine.**—Stroke 18in., revolutions 150 per minute, boiler pressure 90lb. IH.P. = 350, required diameter of cylinders. Assume ratio of cylinders to be 1 to 3, and expansion = 8, back pressure 4lb. per square inch. A = area of low-pressure cylinder, S = stroke of piston, ·385 = multiplier for 8 expansions. Then m.p. = (90 + 15) × ·385 − 4 = 36·4 A ∴ = $\frac{33000 \times 350}{36{\cdot}4 \times s \times 2 \times 150}$ = 705 square inches area for low-pressure piston = 30in. diameter, and $\frac{705}{3}$ = 235 = area for high-pressure cylinder = $17\frac{3}{8}$in. diameter nearly. If it is brake power that is required, then $12\frac{1}{2}$ per cent. should be added to the respective areas.—C. TRATHEN.

[61511.]—**Dynamo.**—You should be able to get nine lamps each 8c.p. actual. These are commonly spoken of as 10c.p. Get 45 volt lamps each requiring ·68 ampère, or, say, 30 watts each. Couple them all in parallel; use Woodhouse and Rawson's lamps—they give a high efficiency and a reasonable life. An Otto gas-engine indicating over 1H.P. should give you the power you require — but you will require about ·75H.P.—on driving-belt to work your lights well, as it will be reasonable to expect so small a dynamo to have only a low efficiency, say, not more than 60 per cent. Run the dynamo with a long belt, and loose as possible, having loose side on top, and put a disc flywheel on dynamo-spindle about 20in. diameter, weighing 70lb. or 80lb. Before buying engine, see it tested, and stipulate for a given power obtainable from belt on flywheel, with a known consumption of gas. An engine tested by me shortly only gave out 48 per cent. of power (in cylinder) at driving-belt; but there are plenty of good and cheap engines now. You should be careful of advice given by correspondents which they cannot submit through the columns of "Ours." It is a great pity so much gratuitous advertising is done in this way.—OHM.

[61518.]—**Gas - Engines.**—Would Mr. Conry please say what he means by over-hot cylinders?—as our experience is that the hotter the cylinder the more powerful the engine—that is, it takes fewer explosions to do the same work. We were told by one of Messrs. Crossley's men to let the cylinder get pretty hot (of course in reason). Who is right? It seems as the gas-engine is a heatengine, and as any heat passing through the walls of the cylinder is wasted, it is anything but economical to keep the cylinder any cooler than is absolutely necessary. What this is we can't exactly say; but cylinder oils can be had to stand 500 or 600 Fahr. We would also be glad to know what parts of a well-made gas-engine are more lightly built than a steam-engine of similar power. The querist may rest assured that if he strains the engine through overheating, he will want a new cylinder and piston, after which his engine will probably be as good as new.—J. M'G. AND S.

[61533.]—**Speed Wheels.**—"A Country Millwright" would buy the MS. of the book if "M. York" would sell cheap; but he would get more off a publisher than I could give.—A COUNTRY MILLWRIGHT.

[61551.]—**Flow of Water through Pipes.**—I do not see how "St. George" gets his $3\frac{1}{2}$in. diam. He seems to forget that the velocity varies with the diameter as well as the inclination.

Let v = velocity in feet per sec.
d = diam. of pipe in feet

$$\text{Then } v = 97{\cdot}05 \sqrt{\frac{d}{4} \times \frac{1}{100}} - {\cdot}08$$
$$= 97{\cdot}05 \sqrt{{\cdot}005} - {\cdot}08 = 97{\cdot}05 \times {\cdot}0707 - {\cdot}08$$
$$= 6{\cdot}7814\text{ft. per sec.} = \text{velocity in large pipe.}$$

And amount of discharge—

$$= v \times d^2 \times {\cdot}7854 \times 60$$
$$= 6{\cdot}7814 \times 4 \times {\cdot}7854 \times 60$$
$$= 1278\,.\,26 \text{ cubic feet per minute.}$$

Now the smaller pipe must be capable of taking the same amount of water.

Let W = cubic ft. per minute of discharge
P = diam. of pipe in inches
H = head of water in feet
L = length of pipe in feet.

Then, from the above formulæ—

$$D = {\cdot}545 \sqrt[5]{\frac{L \times W^2}{H}}$$
$$= {\cdot}545 \sqrt[5]{20 \times (1278{\cdot}26)^2}$$
$$= {\cdot}545 \sqrt[5]{20 \times 1633949}$$
$$= {\cdot}545 \sqrt[5]{32678980}$$
$$= {\cdot}545 \times 31{\cdot}83$$
$$= 17{\cdot}347\text{in.} = 1{\cdot}4455\text{ft.}$$
$$= \text{diam. required for smaller pipe.}$$

Proof. The velocity in the small pipe may be found from the first equation, taking $d = 1{\cdot}4455$, and inclination 1 in 20, and is 12·9636ft. per sec. And substituting this value of v in the second equation, and $d = 1{\cdot}4455$ft., the discharge will be found to be the same as for the large pipe. I will be glad to explain further if required.—ELAG.

[61548.]—**Shipbuilding.**—I am glad to hear that "Novice's" query was not intended to be funny; but, nevertheless, to a "man capable of answering the question," it will appear very funny indeed. For the question is the "method of boring out stern tube, and getting the ship ready for launching." Now, if any stern tube is bored at all, it is bored in the shop before it is taken to the ship; but, as a matter of fact, it is generally a piece of cast-iron pipe! In the navy it is made, I believe, of brass or gunmetal; but even then there is no necessity for boring it, as it is in reality little more than a water casing for the tail-shaft. In the navy the tail-shaft is usually cased with brass or gunmetal, and, therefore, to prevent galvanic action the stern tube is of the same, although it is then encased in an iron cover. The hole in the body post is generally roughly bored before the stern frame is erected, and it is finished when the stern tube is fitted, which cannot be done until the "lines" of the machinery can be accu-

rately centred. The stern tube, too, is fitted with bearings of lignum vitæ, so that the tail shaft does not rub against the interior surface of the stern tube, and there can, therefore, be no necessity to "bore" the latter. The questions are, however, of too special and technical a character to be worth much space in these columns, especially the method of getting the ship ready for launching. Perhaps the querist will state whether or not he found the query in an examination paper, for if he did, it is one of those catch questions which are employed by examiners to test whether the candidate has been merely crammed or has definite and apprehensive knowledge. If after this explanation "Novice" experiences any further difficulty, no doubt some of your readers will be ready to help him.—VIDEO.

[61560.]—**Engineering.**—I think "J. H." has looked at the above question in a very unfair way. He writes from an employer's idea, and not viewing the subject as an unprejudiced person would do. Not only that, but perhaps he will think differently when he reflects that there are both large works and small works. In the former, several descriptions of engines may be constructed during the pupil's stay in the shops, and plenty of each sort may be sent out, thus allowing any pupil ample opportunities for gaining thorough practical knowledge of his subject; but in the case referred to there are not more than 150 men employed, and such classes of work as compound engines, condensers, &c., &c., are rarely seen in the works, and then it is a case of "look, but don't touch." Speaking collectively, pupils to the engineering profession do not get the advantages their premium would warrant; and I may add that it is not a case of gentlemen who wish to be non-workers, as you put it. I quite agree with you that every pupil should do rough work; but I am sure nothing but rough work is rather monotonous, not to say unedifying. I am rather reminded of the Duke's remarks in "Patience" anent "toffee." Perhaps someone else will take this subject up.—DISGUSTED.

[61571.]—**Organ Accordion.**—In reference to the above question asked by "Derfla," and answered by G. Fryer, if Mr. Fryer would kindly send particulars for insertion in the "E. M.," he would confer a favour on another reader who has an instrument sadly out of repair.—JOSEPH E. KEATS.

[61574.]—**The Calculus.**—In common, I have no doubt, with many readers of the ENGLISH MECHANIC, I have read with great interest the explanations of the several correspondents who have attempted to lessen "Tyro's" difficulty, for I have felt, and to some extent still feel, the difficulty he refers to. The numerical illustration of "M.I.C.E." is beautifully clear, and has removed much of the difficulty which, like most beginners, I felt; but I am not able wholly to follow him when he puts his illustration in the dress of the calculus. The following extract contains my difficulty: "The space has, therefore, expanded Δy square feet in $\frac{\Delta x}{3}$ seconds, or $3\,\frac{\Delta y}{\Delta x}$ in one second." How does the increment of x become the divisor in the last expression? Is it too much to ask of "M.I.C.E." that he will explain these symbols in words? Young students of the calculus have to encounter what seem to be very contradictory statements with respect to the notation of the calculus. For example, Young says, p. 5: "The expressions $\frac{dy}{dx}$ and $\frac{dz}{dy}$ have, we see, the advantage over the symbol $\frac{o}{o}$ of particularising the function and the independent variable under consideration, and of thus restricting its signification; and this, it must be remembered, is all that distinguishes $\frac{dy}{dx}$ or $\frac{dz}{dy}$ from $\frac{o}{o}$ for dy, dx, dz, are each absolutely o." Ritchie says, 1st edition, p. 42: "The differential of the independent variable when we are employing real quantities is either a part of the variable itself, or we may take it equal to the whole variable, or even twice, three times, or any number of times of the variable. The differential of the function is also a part of the function, or it may be equal to it, or even greater." To a beginner these two statements appear contradictory.—ANOTHER TYRO.

[61574.]—**The Calculus.**—"Tyro" should try to obtain and read the first volume of Prof. Bartholomew Price's "Infinitesimal Calculus." This is a work which is not nearly so widely read as it deserves to be. Prof. Price being an Oxford man, and the sister university having such a reputation for mathematics, few people care to look farther afield than the Cambridge mathematical textbooks. Most of these latter are so brief and business-like that they become repulsive to the unaided beginner. But in Prof. Price's four goodly volumes "talk," as the Cambridge students call it, is not so much eschewed, and the result is that the work is more readable and intelligible than most of the green volumes we are all familiar with. The work is published at the Oxford University Press.—CALCULUS.

[61575.]—**Indicator Diagram.**—To "T. C., Bristol."—Having done what you suggested some days ago, I inclose results, and hope to have a thorough analysis given of the same, and also to receive any suggestion how to improve matters. I would gladly send samples of diagrams, but they would be useless if served by our editor as he generally serves them—viz., reduce them to microscopic size and never say a word about it; but, still, the full particulars following, which were carefully taken, will, I hope, prove useful to others besides myself:

	First day jacket on.	Second day jacket off.
Total hours run	17·	21½
Average per minute	19·15	19·11
Total coal, gross	3696lb.	5460lb.
Ashes	132lb.	184lb.
Feed water	2358gal.	3700gal.
Evaporation	6·48lb.	6·77lb.
Injection at 50°	52·275gal.	65·415gal.
Av. press. 3 sets of cards	10·69lb.	10·704
I.H.P.	59·36	61·34
Coal per I.H.P. gross	3·66lb.	4·14
" " net	3·55lb.	4·00
Expansions	4·71	4·1
Duty	62·470000	55·440000
Feed per I.H.P. per hour	23·71lb.	27·08lb.
Efficiency	·68	·66

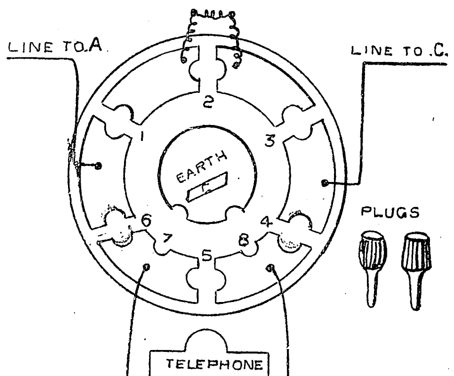
—WATER THUMPER.

[61579.]—**Storage Cells.**—Instructions for forming Planté cells have been given dozens of times. Look up your indices. The process of formation takes weeks, don't forget that; you seem to think it is done in a few hours. Gas is given off during the whole time. It comes away in torrents after the charging has been unduly prolonged. As you do not say what you are charging with or what power, I cannot advise you how to couple up. If your source has high E.M.F. and low current, couple your cells in series. If the opposite, couple in parallel. The soaking of the plates in nitric acid is a very doubtful method, the motive, of course, is to get the lead into a porous condition; but I never found it any advantage. If you are endeavouring to form the plates with a battery, it is almost hopeless; you want a dynamo. —C. D. R.

[61579.]—**Storage Cells.**—"Another Reader" had better place his small accumulators in separate cells, there being always great danger of leakage through partitions such as he describes. When the minium ($2PbO,PbO_2$) on his plates has been allowed to get thoroughly dry, they might be immersed for a few minutes in a very strong mixture of sulphuric acid and water. This process renders the active material quite hard and insoluble, the plates being then in a condition to be placed in the forming solution without danger of their disintegrating. The following method I have found answer remarkably well in the formation of small storage-cell plates: After pasting on the minium, put them in a warm and dry place, and allow to get quite hard; then bind each plate round with ordinary cotton tape, so as to form a mechanical means of keeping the active material from falling down when placed in the liquid. The five plates may then be held firmly together by an indiarubber band or some tape. The poles should then be connected-up temporarily, as in the finished cell; place in a solution of 1 part sulphuric acid and 5 parts water, and send through a current of, say, 1·5 ampère for about 10 hours; then take the plates out and carefully mark them, whether + or −. On removing the tapes, the minium will be found to be quite formed and hard. Next join up poles permanently, and place them in a solution of 1 part acid and 10 parts water, and finish off the charging with the same strength of current—viz., 1·5 ampère. The charging should be continued until the solution assumes a milky appearance. A cell of the dimensions you give, and if the plates are not more than 5mm. apart, should only have an internal resistance of 0·3 ohm. The E.M.F. being fully 2 volts, you would, therefore, get approximately 60 ampères on short circuit, or a safe and steady discharge of 1 ampère for 10 hours. In charging, too large a current causes the plates to break up, and do not forget that a potential of 2·5 volts is required to charge such a cell. To fully charge your five cells in series it would take an E.M.F. of 12·5 volts, and a current of 1·5 ampère, for about 10 hours. If in parallel, 2·5 volts and 7·5 ampères for the same period. Avoid discharging at too rapid a rate, and stop as soon as the potential shows an appreciable fall.—J. T. N.

[61579.]—**Storage Cells.**—What means have you adopted to tell whether you are forming the cells or not? I see you give no particulars except the size of plates and number of cells. You say you have spent "some time with a good current"; but you do not mention what you mean by "some time," or what you consider a "good current." As far as I can gather, you are going on all right, and have simply to continue; but as you do not particularise, I am, of course, unable to say what result you are getting. I know, however, that nearly all amateurs and many young professionals are under the impression that all that is necessary to produce a storage cell lighting a handful of lamps for seven or eight hours is to put a couple of plates of plain lead into an acid bath, and show them a couple of Bunsen jars. Perhaps your current is not nearly sufficient, and unless you charge through an ammeter of some sort, how do you know what you are putting through the cells? A man once showed me a set of E.P.S. cells, and asked me why he could not get any light out of them, assuring me he had been putting 15 ampères through for 75 hours; but when I looked at the dynamo I saw at once, by the absence of even the tiniest spark, that it was spinning but not generating any current. Further examination revealed the little circumstance that one brush, through the spring being too weak, did not make an electrical contact at all unless pressed down with the fingers, and coupling this with the information that the machine had not been touched during the 75 hours, it appeared that during all that time not 1 ampère had been put through the cells. I could mention dozens of instances of this sort. Charging cells without having any measuring instrument in circuit is simply haphazard work, and where the dynamo is driven off counter-shafting having a lot of things on it, the engine will not give any indication, as a separate engine will often do. Storage cells should never be connected in parallel to charge them. Indeed, with most constructions of dynamos and batteries, you cannot charge them in parallel. Even five cells in series is far too small an external resistance for most dynamos or batteries to work with. I should not be surprised if you were wasting three-fourths of your power, as I perceive, from the dimensions to which you made your battery, that you are not accustomed to storage cells. Your cells are too large for pocket batteries, and not large enough for practical lighting work. The gas coming off as soon as you start is quite regular. It always does at the commencement of formation, as you would readily comprehend if you understood the chemical and electrical actions of the accumulator. You do not say if you have reversed your current at all. The best advice I can give you is to refer you to a paper I have written but not published yet, giving an explanation of the construction and nature of storage cells, and the process of "forming." I had so many questions about them that I at last compiled it as being more satisfactory than giving a lot of disconnected scraps of information which might not fit together in the minds of those they were addressed to. If you like to write to me at my address, I can furnish you with this.—EDWARD CONRY.

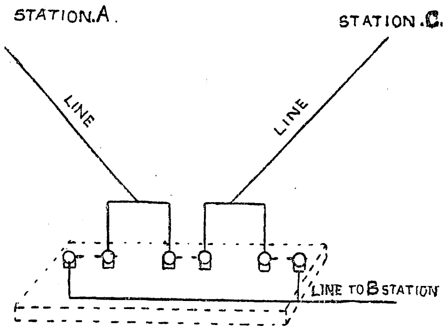
[61581.]—**Telephone Switch.**—Perhaps the following will suit "Enswitched":—Six pieces of brass of any handy size are fixed to the outer edge of a circular base of wood or ebonite, and in the centre is fixed a circular piece of brass, so as to leave ½in. space from outer set of brasses. I ought here to say that you will require another bell, or, preferably, a relay, to be in circuit when A and C are in communication. Two switch plugs must be



made to fit any part of the switch holes, and used as follows:—Insert one plug in hole No. 1, the other plug in No. 3; then A and C are through, and may ring the bell at B when they have finished. Plug holes 4 and 7, then B and C are through; plug holes 6 and 8, then A and B are through; plug holes 6 and 4, then A, B, and C are through, B being intermediate. Now, the central brass plate must remain permanently earthed, as shown,

with other connections, on rough sketch above.—J. FLETCHER, Burnley.

[61581.]—**Telephone Switch.**—"Enswitched" will find that mounting three single-plug switches on a board, and connecting, as in rough sketch,



forms a very simple method of commutation. I have installed three stations, controlled in a like manner, and do not find any difficulty, for B can always ascertain, by switching in his instrument, if A and C are in communication or not.—H. B. EDWARDS.

[61585.]—**Polishing Fretwork.**—Most people in beginning this useful and interesting work fail from one or more of the following reasons:—Not sizing the wood, using too much oil on wood before beginning to polish, beginning before oil has had time to dry in, using too much oil when polishing, or using the polish too thick. I had the same faults to contend with, but got a few hints from an old and clever polisher who was at work on the new pitch-pine seats and fittings of a place of worship. He said to me, You can always get a better polish on wood from the plane than you can after glass-cloth; but you must glass-cloth over after cutting and filing on account of the edges of cut being often rough after saw. He advised me to cut outside with fine saw, and after cutting or filing off any rough places and rubbing over with a piece of partly worn out glass-cloth, to rub over with a pad slightly moistened with oil, and on outside edges, then size over with thin glue size, leave until dry; then do the edges over with varnish, and when thoroughly dry begin to polish. By so doing you avoid the ridge of polish on edges. Use only a suspicion of oil on pad, and let one coat of polish thoroughly dry before applying another.—J. I. S.

[61588.]—**Brass-Cleaning Composition.**—I asked one of the G.N. carriage cleaners at Peterborough what the composition was that was used for cleaning the carriage handles, &c., and he informed me that it was petroleum and Bath brick. —E. E. HIBLING, Peterborough.

[61594.]—**Walcot Battery.**—Perhaps the best method of standardising a tangent galvanometer would be by the electrolysis of silver or copper, preferably copper. If copper, proceed thus: Weigh your gain plates carefully in a chemical balance, note your zero, and keep the galvanometer pointer steady on some fixed point, by means of a rheostat or other variable resistance. Accurately time the duration of electrolytic action, and when finished take the plates out and thoroughly wash and dry them. Weigh gain plates, and note the amount of gain in grammes. The current may then be calculated from the following formula—

$$\text{Current} = \frac{W}{TK}$$

where W is the total gain in grammes
T is the duration of electrolysis in seconds
K is the electro-chemical equivalent of copper

The electro-chemical equivalent of copper may be taken as ·0003287 grammes per coloumb. The time for a trustworthy electrolysis should not be less than one hour; the size of plate to insure a good and adherent deposit should be 50 square centimètres per ampère. The best electrolysing solution is a saturated solution of sulphate of copper, to which is added a few drops of sulphuric acid.—J. T. N.

[61589.]—**Coal Economy.**—The answer of your correspondent, "Nun. Dor.," to my inquiry is exactly what I expected. If in his original letter, of January 14th, he had contented himself with merely expressing his opinion that 900 tons coal seemed a large amount to use in the refining of 1,800 tons sugar, I should not have ventured to intrude upon your space; but when he went further and sneered in a most uncalled for manner at the "hampered industry" of the refiners, and implying that they were ignorant of the very elements of the business, I thought it time to see if "Nun. Dor." had that special knowledge which would warrant him in so doing. It now turns out that he knows nothing whatever about the matter This being so, it is rather uncalled for on his part to attempt to lecture men who are probably quite as well versed in the economy of coal as he is himself. I must apologise to you, sir, for thus troubling you upon a matter which is, after all, of very little interest to your readers, and will conclude by asking "Nun. Dor." not to pass sentence again until he is in full possession of all the "data," to judge "each case on its merits," and, finally, to read carefully the extract from Montaigne which heads your correspondence columns.—SUGAR CANE.

[61599.]—**Gunmetal.**—Soft gunmetal contains 8 tin to 92 of copper; hard gunmetal, 18 tin to 82 copper.—BOGOT.

[61599.]—**Gunmetal.**—"Blacksmith's" query seems to me rather indefinite. Does he wish to know the proportions of copper and tin requisite to make gunmetal; or, only the method employed in mixing them to form the alloy? Gunmetals may be made of all qualities and shades of colour, by varying the proportions of copper and tin. The following are a few mixtures used in the trade: 8 parts of copper to 1 part of tin, 90 per cent. of copper to 10 per cent. of tin, 90 to 90½ parts of copper, and from 9 to 9½ parts of tin. A very good metal for turning purposes is obtained with ⅚ of copper to ⅙ of tin, by weight. The last would probably answer "Blacksmith's" purpose best. Melt your copper in a crucible, then add your tin; keep stirring the while with a poker, so as to thoroughly mix the metals. We used to lift our crucibles, containing the melted copper, out of the furnace, then add the tin, and if hot enough, after mixing (according to the kinds of castings) cast straight away into the moulds. By getting the copper fairly hot, this is easily accomplished.—W. H. KOPE.

[61612.]—**Food for Animals.**—"Thomas" will not be very successful in greatly increasing the framework of the animal beyond what is ordinary unless he goes in for a long course of careful selection in that direction. The power of appropriating food is greater in the pig than in any other animal, hence the reason it thrives on food which would be unsuitable for other animals. The bony framework is best improved by foods rich in ash and albuminoids, such as malt dust and bran. The chaff of wheat, barley, and oats is rich in ash constituents. Very little profit can be made in keeping pigs unless their food is well looked after, and if much meal or other food has to be purchased for them they may soon become a source of loss. Milk greatly aids in fattening. Mr. Mechi, in his "Sayings and Doings," recommends miller's middlings and toppings as a useful food for young pigs. Seeing that he farmed for profit, and had at one time 360 or more pigs, "Thomas" cannot do better than follow his advice.—S. FORD.

[61617.]—**Removing Ink Blots.**—Two correspondents, p. 530, say that a solution of chloride of lime will remove ink marks from paper? Have they ever succeeded in so removing them?—ERASER.

[61627.]—**Boring Hard Wood.**—I have a set of 1in. to $\frac{1}{32}$in. borers, which are fluted, not "twist." They make a splendid hole indiscriminately in hard and soft wood, in iron, and in brass. The evenness, trueness, and smoothness in the hole is remarkable. I should prefer a bit of hard, not soft, underneath the piece being bored.—R. S. T.

[61634.]—**Will o' the Wisp.**—Mr. Conry is, I think, mistaken in putting "St. Elmo's Fire" under this head. It is usually considered as a brush discharge of electricity from the most exposed points of a ship's spars, at a time when there is a considerable difference of electric potential between the earth and air or clouds above the ship. —J. BROWN, Belfast.

[61634.]—**Will o' the Wisp.**—All four replies are quite inconsistent with either of Mr. Conry's two contradictory theories. The "St. Elmo's fire of the sailors," appearing only at pointed conductors, is an electric brush discharge, and has nothing to do with any burning gas; moreover, to produce the marsh flames neither sulphuretted nor carburetted hydrogen" ("marsh gas") will suffice alone, as they would not ignite spontaneously. There must be some phosphuretted hydrogen to account for the ignition.—E. L. G.

[61634.]—**Will o' the Wisp** is due to the ignition of marsh gas evolved from decaying animal and vegetable matter by spontaneously inflammable phosphoretted hydrogen; it has not the slightest connection with or similarity to St. Elmo's fire, which is an escape of electricity from the masthead of a vessel as a brush discharge. "Light sulphuretted hydrogen" is a gas which has not yet been described in works on chemistry; perhaps Mr. Conry will favour us with an account of its preparation and properties.—WM. JOHN GREY, F.C.S., Newcastle-on-Tyne.

[61634.]—**Will o' the Wisp.**—I see that your correspondent, Mr. Conry, suggests that this is "light sulphuretted hydrogen" (I suppose "carburetted" is meant), and is analogous to St. Elmo's fire seen playing round ships' rigging in bad weather. It is rather difficult to conceive how the "light sulphuretted hydrogen" contrives to get round the mastheads, unless the ship has a cargo of rotten eggs on board. Most people regard the phenomenon as being a discharge of electricity. I always thought that the Will o' the Wisp was marsh-gas, or "fire-damp" (CH_4), which is produced by decaying vegetable matter. I have often myself ignited this gas, after stirring up the bottom of a stagnant pond full of dead leaves, thus forming an artificial Will o' the Wisp.—REYMOND.

[61634.]—**Will o' the Wisp.**—We have been rather amused on reading the answers to this question, as it has been a regular occurrence (ever since I can remember) to see the "Jinny Wisp" (as the people call it here). I have seen as many as two or three together bobbing up and down, and last year my father called me out one damp, foggy night to see one in front of our house. There are many ghostly stories told of unwary or half-drunken travellers being decoyed into swamps by the deceitful Jinny. As a child I was very afraid of Will o' the Wisp, and was very thankful to have someone with me when I saw it. I don't think they are so numerous now, nor so bright and glowing; I should think this is owing to the better drainage. But on a damp and foggy night they are still to be seen, and I should say there is hardly a fen man who has not seen one, and who would not think anyone terribly behind hand who had not.—A LINCOLNSHIRE LASS.

[61634.]—**Will o' the Wisp.**—In 1864 I was in a boat drifting down a river in North New Zealand (Kaipara) at about 9 p.m. Approaching the landing in the dark, we had called for a man on shore to bring a light to guide us to the wharf. While waiting I saw a bluish light which I supposed was the candle; but it floated across the river at about 6ft. or 8ft. above the water, not "dancing up and down," but moving steadily. It went into a swamp on the lower bank of the river; but before it disappeared the real candle was brought to the river bank, and the contrast between the two lights was very striking. The candle gave a yellow light, while the Will o' the wisp was decidedly bluish, and looked as if seen through fog. In the dense bush on a very dark night I have also seen a surface more than a yard in diameter shining with phosphorescence, which on examination proved to be decaying leaves dropped from the Ti palm (cabbage-tree). In fresh water rivers trails of phosphorescent light may be seen issuing from weeds under the water, the light seeming like oil leaving the plants and floating down with the current. At a depth of some feet blotches of this light sometimes look ghastly enough, and have no doubt contributed to the Maori's belief in "Taniwhas," or water monsters, especially since the snags on which the water weeds grow frequently upset the boat.—T. F. S. T.

[61642.]—**A Good Illuminant.**—If "Like to Know" would take a little trouble he might easily know all he wants about the Welsbach light, for it was described in No. 1139, and I believe previously, while I notice now that it is referred to in the Scientific News on p. 518. It is for the present the most successful of many attempts to construct a bonnet or cap for a Bunsen burner which can be raised to a state of incandescence without prematurely crumbling up. I notice that one of the professional journals says: "The light itself we have examined carefully, and consider it a most efficient and agreeable form of artificial light"—to which the inventor might reply, "Thank you, for nothing; that went without saying." What is wanted is commendation like that given by the *Times*, which boldly stated that the new light "burns up all the impurities of the gas, giving off no carbon and no sulphur, and comparatively little heat." It will, of course, give off just as much sulphur or sulphurous compounds as the gas enables it to do, for it contains no sulphur in itself, and it can't get rid of what may be in the gas, and as to "comparatively little heat" it depends on what is meant. The heat produced is exactly that due to the consumption of so much gas: it seems little, because, as is well known, all incandescent systems give a powerful light on a small consumption of gas.—NUN. DOR.

[61643.]—**Boiler Query.**—The following formula will give the temperature, T, of steam at any pressure, P:—

$$T = \frac{2938{\cdot}16}{6{\cdot}1993544 - \log. P} - 371{\cdot}85$$

T = for 45lb. = 274·4° Fahr., and
for 65lb. = 298·0° „

It will be seen from the above that the temperature of steam increases with the pressure. Other things being equal, of course the higher pressure would serve your purpose best.—ELAG.

[61643.]—**Boiler Query.**—The boiler at 65lb. would show the greatest temperature by thermometer—viz., 312°F. that at 45lb. being 292·7°F.; but

the total heat in the steam would be nearly the same in both cases, as there is less latent heat in that at the higher pressure, the difference being not more than 1°F. Consequently, the same weight of steam in either case would make the same weight of water boil in an open cistern, an open cistern being intended, I presume. If, however, it were a closed vessel, of course the higher pressure would give the higher temperature.—T. C., Bristol.

[61643.]—**Boiler Query.**—As the pressure of the steam increases, so also does the sensible heat. According to Regnault, the following table shows the increase of the sensible, the decrease of the latent, and the increase of the total heat at different pressures rising by an atmosphere:—

Gross Pressure.	Sensible Heat.	Latent Heat.	Total Heat.
lb.	°	°	°
15	212	966·2	1178·2
30	251	939·	1190·
45	275	922·7	1197·7
60	294	909·2	1203·2
75	309	898·5	1207·5

From this you will be able to answer your other query.—W. HOLDER, Newport, Mon.

[61647.]—**American Organ.**—The 8ft. row of reeds should be voiced to produce a round quality of tone. It requires artistic skill to do this as it should be done. The principal and flute (4ft. set) should be voiced a trifle louder than the 8ft. row. A pleasing variety of tone can be obtained by having the 16ft. treble set voiced to imitate the clarionet. The other 8ft. treble set can be voiced according to taste. In a large number of reed organs the extra 8ft. treble set of reeds are put slightly out of tune with those of the Melodia or other 8ft. treble reeds, so as to form a celeste, or vox jubilante, as it is sometimes called. Different makers attach different names to some of the stops, but the mere name, as a rule, is not much to be guided by. If you make your bellows to the dimensions given below it will answer admirably:—Centre board, 3ft. by 2ft. 4in. by 1in.; reservoir board, 3ft. by 2ft. by 1in.; feeders, each 19in. by 16in. by ⅜in., of good and well-seasoned pine. The reservoir board may be allowed to open from 7in. to 8in. I should not recommend the bellows to be made smaller than the above-quoted dimensions, and it will not matter if the bellows are made a little larger. The best rule is, make the bellows as large as possible, but within reasonable limits.—G. FRYER, Gorse-lane, Swansea.

[61647.]—**American Organ.**—It would be as well if "J. S." procured his rather peculiar "board" before he asks what kind of voicing the reeds are to have. It is to have a full row of 8ft., and another of 4ft. "in front," therefore presumably one on the top of the other, with the two half-rows at the back, one on the other, so as to be in one block. Or does "J. S." mean that the two full rows are to be like an ordinary two-row board, with the half-rows at the back of the soundboard? The latter arrangement will involve the use of two sets of pallets, with the lever arrangement in the chest, whereas, if all the sets are in one block, one set of pallets will answer. It seems strange, too, that he should be thinking of having three octaves of 16ft., and two and a half octaves of 8ft. in treble. Why not have both alike? For his pedal set, too, why not have the full complement of thirty notes, instead of only two octaves? If "J. S." will get such a "board" as he describes, and give the dimensions, no doubt he will obtain useful advice; but I doubt whether so nondescript an arrangement can be obtained, except by special order. However, his 8ft. row should be voiced to the diapason tone, as it is the groundwork of the instrument, and he can then make the half-rows what he likes. As to size of bellows, the golden rule is to make them as large as possible—that is, the size depends on that of the board or of the case. If "J. S." is going to make his own cavity boards, he can make them to suit his designs; but I should think he would find one of the stock arrangements answer his purpose, and I see several advertisers are now prepared to supply them. As he wants pedals, I should advise him to have a C scale board, and then the instrument will at least be useful for practice purposes, if he fails to make it do something more than "pray"—to quote the amusing criticism of our friend the "Country Solicitor." Briefly, I would advise "J. S." to determine what sized board he will have, and then if he will describe its arrangement and dimensions, I have no doubt he will obtain all the assistance he needs.—ORGANON.

[61648.]—**Battery for Lamp.**—The voltage of the bichromate cell as described is about 1·8 volt. Hence, to get the required voltage at least five cells would be required, and as the resistance of the cell is rather large, so that the current is not very large, it would be well to err on the side of excess and use at least six cells. If the carbons are raised as well as the zincs, the battery will remain in good working order much longer than if they be left immersed, as the acid soon corrodes the connections. To carry the current 10 yards without appreciable loss, use No. 14 copper. Ten yards of this will not have a greater resistance than ·06 of an ohm, while 10 yards of No. 16 would measure ·1 of an ohm.—S. BOTTONE.

[61648.]—**Battery for Lamp.**—If the battery was freshly charged, most likely six cells of your battery in series and each cell made up of three in parallel would be found sufficient. The E.M.F. of one of your cells would be about 1·5 volt. The battery would absorb about one volt, and if only six cells in series were used, the E.M.F. at terminals of battery would be about eight volts. The carbons of a bichrome battery do not need to be removed from the solution, as there is no action on them. The fault, however, is that the outer solution diffuses itself through the porous cell, and unless the porous cell be removed when the zinc is taken out, the solution inside and out of it is the same, and therefore it is useless. The leads should be of No. 18 Cu. I.R. and braided; their total resistance will be about ·3 or so of an ohm; this, with a current of two ampères will absorb ·6 of a volt; so to work well seven cells should be coupled in series, especially as the eight-volt Shippey lamps take nine volts to work properly, and, as you know, it is usual to overrun battery lamps slightly.—IOTA.

[61648.]—**Battery for Lamp.**—What a host of queries of this description there are in these columns week after week. There may be a distinction, but scarcely a difference. You say the lamp is an eight-volt one. Now as the E.M.F. of a bichromate battery (or rather cell) is, roughly speaking, two volts, you would theoretically require four of these cells in series; but practically, you must have five. This settles the E.M.F. part. The rest will depend on the porous pots to a considerable extent. If these are in good condition and of low resistance, the five cells in series will light your lamp; but if they won't, then you will know that your battery does not furnish sufficient current, and you must make up another five cells and connect the whole lot in two series of five cells in each series. When you have made your first five cells, connect them to your lamp first with the porous cells in use, and then without the porous cells, and I think that in the latter case the lamp will light well. It is not necessary to lift the carbons out of the solution, and if you are going to lift the zincs out I should decidedly do away with porous pots. No. 20 wire will do, and will not necessitate any additional battery power.—W. HOLDER, Newport, Mon.

[61651.]—**Induction Coil—Testing Continuity.**—Attach one terminal of the secondary to one binding screw of my half-crown galvanometer. Connect the other terminal of the secondary to a single-cell bichromate battery. Now touch the other binding screw of the galvanometer with the free pole of the battery. If the wire is continuous you will get a deflection; if not, the needle will remain motionless.—S. BOTTONE.

[61651.]—**Induction Coil.**—Connect in series the secondary wire, a battery, and an ordinary galvanometer, and if, on making the circuit complete, there is no movement of the galvanometer-needle, the secondary of the coil must be broken. Of course, as the secondary is of high resistance, the battery had better consist of three or four cells coupled up in series, and the galvanometer should have a good number of turns of wire on it.—VIR SAPIENTIÆ.

[61651.]—**Induction Coil.**—I think I can assure "J. P. Aigburth" that his secondary wire is continuous still, or he would get no spark at all. Provided he is using the same battery as formerly, and the connections (especially those with the condenser) are all right and clean, his shortened spark denotes that too much battery power has been used, and that, in consequence, the secondary has burst through its insulation, and the coil is short-circuited. This fault will increase, and the only remedy is unwinding and remaking. As it was made some years ago, was guttapercha tissue used to insulate the secondary layers? If so, the failure of that unreliable substance is at the bottom of the mischief.—B. HARCOURT.

[61651.]—**Induction Coil.**—The fact of your getting a spark at all is sufficient to show that the secondary has not parted. Can you not try it with a telephone or a galvanometer? Or if these are not to hand, you can use the chemical test for weak currents, which consists of dissolving a little iodide of potassium in some water and adding a little starch paste. You have now a very sensitive electrolyte which will turn an indigo-blue colour at the anode when a very feeble current passes through it. But this is not necessery if you get a spark at all. Perhaps the coil is damp; if so, this would account in a great measure for its unsatisfactory performance.—W. HOLDER, Newport, Mon.

[61652.]—**Screw-Cutting.**—Your best plan is to make a template yourself for each pitch. If re-required of exact form, a chaser is far the best plan for finishing cut. You would find it difficult to grind the tools to the special template, as it would be formed of two barely quarter circles united by a straight line, the ordinary gauge, as you know, being a straight line (speaking of one edge of the template only).—T. C., Bristol.

[61655.]—**Gold Size.**—Gold size is prepared from ½lb. of linseed oil with 2oz. of gum animi; the latter is reduced to powder, and gradually added to the oil while being heated in a flask, stirring it after every addition until the whole lot is dissolved. The mixture is boiled until a small quantity when taken out is somewhat thicker than tar, and the whole is strained through a coarse cloth. When used it must be ground with as much vermilion as will render it opaque, and at the same time be diluted with oil of turpentine, so as to make it work freely with the pencil. Somehow I do not think that this is what you want to know; but at the same time it is the only gold size I know of, and you may find it useful.—W. HOLDER, Newport, Mon.

[61656.]—**Amalgamating Copper Wires.**—I always dip wire in nitric acid, then in mercury.—AN A.S.T.E.

[61656.]—**Amalgamating Copper Wire.**—Rub the wire with fine glass-paper moistened with solution of nitrate of mercury. Then rub on some mercury also.—J. BROWN, Belfast.

[61656.]—**Amalgamating Copper Wire.**—Dissolve as much mercury in nitric acid (strong) as it will take up, then add about as much more acid. If the wire is clean, a dip in this will at once amalgamate thoroughly. It must, of course, be at once well washed in plenty of water to remove any acid.—OHM.

[61656.]—**Amalgamating Copper Wire.**—First clean the ends of the wire by rubbing them with emery or glass paper. Then dip the ends of the wire into dilute sulphuric acid (prepared by adding slowly one part of strong sulphuric acid to eight parts of water), and subsequently dip them into mercury, and, by means of a piece of rag on the end of a stick, the mercury can be rubbed on to the wire.—VIR SAPIENTIÆ.

[61656.]—**Amalgamating Copper Wire.**—Clean the ends by means of coarse emery cloth, so as to leave plenty of scratches or crevices in the copper. Then dip into nitric acid for about a minute or two, and finally into the mercury in a test-tube. If you like you can give them a preliminary coating by immersing them in a solution of mercury dissolved in strong nitric acid, and afterwards proceed in the usual way.—W. HOLDER, Newport, Mon.

[61656.]—**Copper Wire.**—The ends of copper wires are easily amalgamated if they are dipped for a moment into an acid solution of nitrate of mercury and then into mercury, which they take up with great ease.—IOTA.

[61660.]—**Picking Lever Locks.**—"J. W. R." should take a term under some "Bill Sykes," who would be the best authority on this subject. It is rather a dangerous vocation, and often leads to a term of retirement in a county institution.—J. I. S.

[61661.]—**Coil.**—TO S. BOTTONE.—Your coil is entirely wrong. First, the clapper must have an iron head, not brass; secondly, the core must not be a "temporary magnet," if by that you mean a soft iron rod; but a bundle of iron wires. The connections from the binders from base to primary screws, should be copper. The quantities of both primary and secondary for a shocking coil are excessive.—S. BOTTONE.

[61664.]—**Partial Silvering.**—Copal varnish prevents deposits occurring on any place it is applied to, and is much used for "stopping off." W. HOLDER, Newport, Mon.

[61666.]—**Non-conductor.**—How would a paste composed of concentrated solution of silicate of soda and ground glass do? It is easily tried, and is inexpensive.—W. HOLDER, Newport, Mon.

[61666.] — **Non-conductor Insoluble in Ether.**—That insolvent (at least simple, so-called "sulphuric ether") will neither attack indiarubber nor guttapercha.—E. L. G.

[61666.] — **Non-conductor Insoluble in Ether.**—Glue is insoluble in ether. I have used the following cement for closing heads in a vessel to contain ether:—Soften an ounce of glue in water, pour off the water and add an ounce of treacle; heat, mix, and apply hot with a brush. It never gets quite dry; but it seems quite impervious to the ether. Querist does not say of what it is to be a non-conductor.—J. BROWN, Belfast.

[61669.]—**Sharpening Carpenters' Tools.**—A friend of mine has a circular oilstone on a lathe; but it is messy and inconvenient. It throws the oil about, and the tool is liable to dig into it. The comparatively small amount of sharpening, or setting, to be done after the tool has been properly ground seems more conveniently done on the usual flat stone.—J. BROWN, Belfast.

[61669.]—**Sharpening Carpenters' Tools.**—I had, and have, a circular (small) Arkansas stone, perhaps a little harder than Turkey. For some purposes it acts well. I tried not only the periphery, but the flat surface. I was not satisfied. I also had a large 9in. or 10in. Welsh stone and made it as true as a die with Carbonado; but I sold the whole thing, as I found a grindstone, and then a coarse flat Arkansas, and then a very fine Arkansas, gave better results.—R. S. T.

[61671.]—**Heating of Wire, &c.**—TO MESSRS. CONRY AND BOTTONE.—A covered wire heats more than an uncovered one. Chloride of calcium is the right thing to use; quicklime is not bad. If you really have half an ampère, you need only put your ammeter in circuit, and notice the deflection it gives, as ½ ampère; so also with the one volt—passed through the voltmeter should give a deflection which must be marked as one volt.—S. BOTTONE.

[61671.]—**Heat in Wire, &c.**—It is quite true that an insulated conductor will carry more current than a wire uncovered and exposed to the atmosphere (see Sprague, p. 300, &c., also Forbes' paper, Telegraph Engineers, &c.) In the newest form of Clarke gas-lighter the drying material is never used; in fact, the form you refer to works just as well without it. Improve the insulator at all points by brushing with benzine or paraffin, and then be careful not to touch with the fingers after cleaning. To calibrate an ammeter, see reply to 61131, p. 352. Having made an ammeter first, then if you have an accurate resistance instrument, you can easily construct a voltmeter.—OHM.

[61672.]—**Electric Lighting.**—TO MR. BOTTONE.—To light twenty 20c.p. lamps, you will need a dynamo (Gramme or Mather-Platt pattern) with a ring armature of about 7in. in diameter. From 1½ to 2H.P. should be ample if the dynamo be a good one. Pulley on dynamo 3in. in diameter. Sheave on engine 3ft. in diameter. Speed of armature from 1,600 to 1,800 per minute. Accumulators not needed. Cable seven or eight strands of No. 20.—S. BOTTONE.

[61673.]—**Dynamo to Light Thirty 20's.**—You will find full instructions for making one of these at pp. 261 and 564, Vol. XLI. of the ENGLISH MECHANIC. I can supply you with a pamphlet if you apply to me.—S. BOTTONE, Carshalton.

[61674.]—**Butterine.**—The simplest method I have found for the detection of animal fats (a method for which, if I recollect, I am indebted to the pages of the MECHANIC) is to rub some of the suspected substance on a piece of calico, set it on fire, and then blow out the flame. If animal fat has been used, the smoke of the smoldering calico will smell like a tallow candle that has been blown out; while if pure butter has been used, it will smell quite sweet. I regret to add there is a strong suspicion that some English farmers have adopted the practice of adulterating their butter with oleomargarine, and we badly want a stringent measure, like that recently passed in America, to protect honest dairy farmers.—DOCTOR MEDICINÆ.

[61675.] — **Cardiac Affections.** — Though "G. F." has not addressed his query to me specially, I will venture to reply. Regurgitation is a purely mechanical matter, and the symptoms are those of "back water." The valves most likely to be affected are the aortic and the mitral. If the former valves become incompetent, the left ventricle will probably increase in bulk and strength, sufficient to compensate for the incompetence, and until it begins to fail there will be usually no general symptoms; when, however, failure of the heart muscle sets in, general dropsy from "back water" will soon supervene. The case of the mitral valve is somewhat different when it is incompetent: the blood at each contraction of the ventricle is driven back upon the lungs, causing engorgement of them and occasional blood-spitting and difficult breathing on exertion. Regurgitation, as I have shown, is not necessarily followed immediately by general or local dropsy. The chief symptoms indicating mitral regurgitation I have already stated. The indication of aortic regurgitation, apart from stethoscopic signs, is the strong pulsation of the enlarged heart; but this may also be due to narrowing of the aortic orifice. Until the heart muscle begins to fail valvular disease may exist without subjective symptom; that is quite unknown to the patient, and is compatible with long life and rude health. Dr. Andrew Clarke gives, in a late number of the *British Medical Journal*, a list of 684 of his patients "in whom there existed chronic valvular disease of the heart, the presence of which was not indicated by symptoms, and did not sensibly interfere with health," and who had consulted him for other ailments. Valvular disease does not tend to produce aneurism, generally speaking. I have endeavoured in the above to avoid technicalities, and to explain the matter simply without going into debatable ground.—DOCTOR MEDICINÆ.

[61678.]—**Violin Bow.**—Drive suitably-placed wire nails in a piece of board, then heat the bow before a fire, and place between said nails until cold. I have not tried this way, but have steamed a bow, with the certain result that the spring or elasticity is not equal to that of a bow shaped to the proper curve as usual.—A., Liverpool.

[61679.] — **Photographs.** — To R. A. R. BENNETT.—Put your positive into a printing frame, film-side upwards, and another dry plate on the top of it, film side downwards, then shut up the frame. Now prop it upright on the table of your dark room, and hold a lighted match just in front of it, and about 2in. or 3in. off, for about 30 seconds, or less, according to the density of the negative. If you use a ruby lamp, simply take the shade off the candle while holding it in front of the frame, and replace it in a few seconds. On developing the plate you will have a negative, bad or good, according to the quality of the positive. This is a good way to make transparencies, using a negative instead of a positive, and some developer that gives black tones. If you want more information, I will do my best to give it you if you will write to me.—R. A. R. BENNETT.

[61681.] — **Electrical Measurement.** — The quantity of electricity conveyed by 1 ampère per second is called one coulomb. The old electrical term veber was exactly the same as the ampère.—OHM.

[61681.] — **Electrical Measurement.** — An ampère per second is the same as the *d* "weber" in its relation to other units; but its exact value is slightly altered, the other units being now the legal ohm and volt, whereas the B.A. unit had a different value, making the ohm ·9889 of what it is now. It is rather difficult to express the difference between an ampère and a coulomb. An ampère per second is a coulomb, and to find the number of coulombs, multiply the current in ampères by the time in seconds. An ampère takes no recognition of time beyond the unit, and it is independent so far of time; but an ampère flowing for n seconds produces n coulombs, or $\phi = C\,t$.—IOTA.

[61681.]—**Electric Measurement.**—The ampère is the practical unit of current, and was formerly called the "veber." The coulomb takes into consideration quantity in this way. It is of the value of one ampère of current per second—thus 10 ampères would transmit in one second 10 coulombs of electric quantity. These units are a never-failing source of annoyance until mastered, and to do that I should advise you to get a little book called "Electrical Units," by J. Swinburne, published by Spon, price about 1s. or 1s. 6d. This will do you more good than any correspondent of the "E.M." can, unless he utilises about four or five columns in explaining the complete system.—W. HOLDER, Newport, Mon.

[61682.]—**Coulomb-meter.**—The exact purpose served by a coulomb-meter is to measure and register the quantity of electricity which may have passed through a circuit in a given time, something after the style of a gas meter. There are two kinds—magnetic and chemical. In the former kind clockwork is brought into play. Do not know price.—W. HOLDER, Newport, Mon.

[61682.]—**Coulomb-Meter.**—A coulomb-meter measures the quantity of electricity that has passed—that is, the current in ampères multiplied by time in seconds (see reply 61681). A simple meter may be made with two copper plates in solution of copper sulphate. The increase of weight of the kathode, divided by the electro-chemical equivalent and by time in seconds, gives the current in ampères, or, if wanted, the coulombs. Ferranti's coulomb-meter is the best, I believe; but it is rather expensive. Any action of the current into which time enters as a factor may be used as a coulomb-meter.—IOTA.

[61685.]—**Spring of Beam.** — What is the meaning of this query? Do you mean how much will it draw the two walls together as the beam gives to the weight?—T. C., Bristol.

[61684.]—**Harmonium.**—The matter of adding a voix celeste stop to any harmonium incurs a certain amount of trouble which very few people care to experience. "H. E. S." gives no description of his instrument; but with regard to the matter of producing a celeste without having the reeds materially out of tune with another set of reeds of the same pitch, the method applies chiefly to American organs, in which case the celeste effect is produced by admitting the air to the reeds in a different direction from the ordinary way. It can be produced in the harmonium by similar means; but it is not quite so effective as in the American organ, although the method is preferable, in some respects, to the usual and objectionable method of putting reeds out of tune in producing the celeste effect.—G. FRYER.

[61687.]—**Water Pressure in Towns.**—In J. and H. Gwynne's Catalogue I have seen drawings of pumps and turbines, or water engines, arranged for water to be sent to a great height from a moderately high actuating source.—S. F. S. T.

[61689.] — **Dynamo.**—All field magnets and cores of dynamo machines are liable to get heated, and this is in every way detrimental to the good working of a dynamo. A machine does not give such a good output when hot as when cold, to say nothing of the risks of destruction by the overheating. Your machine does not get exactly fair play if it is running day and night. If kept perfectly clean it should last for years, but the commutator and the brushes will probably want renewing, as also the bearings. If these points are well attended to, you will not run much risk from the coils fusing: it is a rare occurrence.—W. HOLDER, Newport, Mon.

[61689.]—**Dynamo.**—There is little chance of the coils fusing, unless the dynamo is being driven far beyond its regular output. You should be able to bear your hands on the coils, even when working at its hardest. In case of a short circuit in the leads, and if no safety fuses were in circuit, it would be most likely the armature that would go, and not the field-magnet coils. In some machines the pole-pieces get very hot, and that heats up the field coils. A good machine, taken care of, and cleaned up regularly, should last 20 to 30 years, and many makers guarantee them 15. In rough work, 10 years is not considered bad.—IOTA.

[61689.]—**Dynamo.**—The coils of your dynamo are liable to fuse, but are not likely to do so until, through the continual overheating, the insulation on some adjacent coils is destroyed and a short circuit established. Your machine must be overloaded, or perhaps brushes short-circuiting several bars, or Foucault currents present. Anyhow, give the armature plenty of cold air. A good machine should never get hotter than the hand. A good dynamo, slow speed, should last, with only slight renewals, 40 years. A high speed machine, or one which sparks a good deal, may be ruined in a year.—ARCADIAN, Failsworth.

[61689.]—**Dynamo, Heating of.**—Long before the wire fuses the covering will burn off. A well-made dynamo will last for several years, the plummer blocks and brushes alone requiring renewal, and sometimes the commutator.—S. BOTTONE.

[61689.]—**Heat in Dynamo.**—All dynamos heat, more or less, when at work; but if the heating is excessive there must be something wrong. You should always be quite able to bear your hand on hottest part, and you should not run the machine if the heat exceeds 60° C. Where does the heat appear greatest, in the coils or com.? Any dynamo of good design should be easily maintained at a cost of about 2 per cent. per annum; but, of course, there are dynamos and dynamos.—OHM.

[61690.]—**Improving Coil.**—TO S. BOTTONE.—Rewinding the secondary and basting well with hot paraffin wax, would certainly improve matters.—S. BOTTONE.

[61691.]—**Engine.**—If you have only one ⅝in. hole at each end for posts, they are not near large enough; you should have three such holes. The engine won't be of much service unless you have something like that area. If driven 200 revs. with 60lb. steam and cut off at ¾ stroke, it would give 2½H.P. Flywheel 20in. to 24in. dia., and weight, say, 3cwt.—T. C., Bristol.

[61692.]—**Electric Lighting.**—I think this could be arranged by means of a couple of two-way switches. I will send you a rough sketch of the connections I propose if you feel inclined to advertise your address. In order to avoid such a sneering remark as "C. D. R." made in reference to one of our most talented correspondents, Mr. Conry, I may say that I am not in business, so that it is not to advertise, also that it is not because it would not bear scrutiny, for if "C. D. R." or anyone else likes, I would oblige them with a similar sketch if they really required it.—EVELINE W. HOLDER.

[61693.]—**Water.**—This will depend entirely on the draught you have, and whether you fire easy or hard. Taking the two firegrates combined as 26ft. super., and burning, say, 15lb. coal per foot per hour (that is about 10 tons per week of 62 hours), you would require 70 tons of water, about.—T. C., Bristol.

[61694.]—**Lucigen Light.**—Is not the Lucigen simply creasote blown into a spray by a blast of air, so that a flame of almost any desired height can be obtained? Can anyone give comparative cost with a good arc light?—NUN. DOR.

[61694.]—**Lucigen Light.**—Two can be seen in full operation nightly on some building works opposite the Temple station of the District Railway. Another is at work in Piccadilly at the north-east corner of the Green-park. — R. T. LEWIS.

[61697.]—**Violin Bow Hairing.**—Premising that this requires considerable practice to make a good job, I have seen a professional do it thusly, and also tried it myself; but as the new hair costs, say, 10d., and the sum which is charged here is only 1s., it does not pay an amateur at all to attempt it. First, unscrew bow, dip ends in hot water, and extract the little wood cover by putting on the old hair; take the new lot, place in moderately "warm" water for a couple of minutes to soften it, pinch up the tied end tightly like the letter V and insert the point into the hole, arrange the hair evenly, then replace the wood cover, having a little glue upon it, and leave this until the glue is dry; then wet the hair again in warm water and comb out with a fine comb, tie firmly with waxed thread at the required length, cut off, and burn the end with a lucifer match, which prevents the ends from drawing through the tie; this end is now to be similarly treated as the other was, and fixed into the movable piece of the bow. It is now left to dry thoroughly, and then being screwed up, all loose or crooked-running hairs are trimmed off with a scissors. Never "pull" a hair from a bow, as this loosens the whole of them. Pound a bit of rosin in a piece of paper for the first time of rosining. The new violins are stained previous to polishing with, I believe, umber and sienna, according to taste.—A., Liverpool.

[61700.]—**Nickel Crucibles.**—1. They can be obtained at any tolerably enterprising operative chemists. 2. As far as being unattacked chemically is concerned, they would stand the action of fused alkaline silicates; but have a strong tendency to become covered with scales if heated to such a temperature and in such free contact with air as a muffle affords. If heated in coal-gas flame, they become covered with bulky black flakes if the air be not in large excess. These flakes are mainly composed of carbon, though they also contain nickel; no such formation occurs in the flame of pure hydrogen, so that the carbon evidently comes from the gas, which must therefore be partly dissociated by the action of the nickel. I should expect no such coating to appear if producer gas were used. For more detailed and further information, see the *Chemical News*, No. 1414, December 31st, 1886, and a few following numbers. There you will find several articles and letters, and the whole subject pretty thoroughly discussed.—BERTRAM BLOUNT.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since out last "Practical Ry. Man" has replied to 61083.

Population of France. — The census taken last May, and published on the 6th ult., shows the population of France to be 38,218,000, whereas in December, 1881, it was 37,672,000. This gives an increase of 546,000, whereas in 1881 the increase in five complete years was 766,000. In Paris the increase is only 75,000—namely, from 2,269,000 to 2,344,000 whereas last time it was 280,000. Lyons has the much larger proportionate increase of 25,000—namely, from 376,000 to 401,000. Marseilles has increased from 360,000 to 376,000, Bordeaux from 221,000 to 240,000, Lille from 178,000 to 188,000, Nice from 66,000 to 77,000. Roubaix has increased by 8,000, and Toulouse and Tours each by 700. The other large towns, with the exception of St. Etienne, which has fallen from 123,000 to 117,000, show an increase in no case exceeding 6,000. The 53 cities or towns having more than 30,000 inhabitants, Paris included, show a net increase of 309,000.

QUERIES.

[61701.]—**Gas-Engine.**—I am working in a small printing office, where there is a small gas-engine, a horizontal one (Crossley's silent Otto), about 2½ or 3H.P. I have only worked there three months. The engine went on very well. I started her every morning easily. Slides and gas holes cleaned once a month. On Saturday evening a man cleaned the slides again. I started her on Monday morning; worked well all day to 7 p.m. Next morning went to start her, turned on gas, adjusted the lights, oiled her, filled the lubricator cup that oils the slides, and I could not get her to start, no matter what I did. There was nothing wrong with the gas. Could you tell the cause? Is there a book of instructions sent with these engines? I want to find out for myself, as this man tells me nothing about her. The number is 3168. With two turns of the flywheel she started on Monday morning.—WILLIAM MOORE.

[61702.]—**Turning.**—How would I turn up the face of a battering ram of cast-iron, 18in. long by 10in. square, in a large screw-cutting lathe, 10in. centre?—WEE LADDIE.

[61703.]—**Tempering Saw.** — Would some kind reader of "Ours" tell me of any method of softening cross-cut saw 6in. long? It is so hard that I cannot set it without breaking the teeth.—WEE LADDIE.

[61704.]—**Cocaine.**—Can any of your correspondents inform me as to the proper strength and quantity of the solution of cocaine used in small operations on the teeth and on other parts by subcutaneous injection? Also proper mode of application to the teeth for stopping operations?—C. E. A.

[61705.]—**Faulty Micro. Prism.**—I have a binocular microscope, and something is wrong with the prism; with the ¼in. and ½in. object-glasses, the field is very obscure, especially at the edges. If I push the prism to the right, so as to favour the upright tube, the left is clouded, and shows very faintly. With the 1in. glass I get better results, especially with opaque objects and using the condenser; but even then there is a lack of light. The fault must be in the prism, as without it, and using the upright tube only, I obtain all that can be desired. Will some reader help me, and say what a prism costs? I am a mechanic, and could do slight alterations myself if I knew how to proceed.—M. SIRP.

[61706.]—**G. and S.W. Locos.**—Would Mr. Stretton, or any other correspondent, kindly give me a diagram of the above?—C. BAYLEY.

[61707.]—**Centre of Pressure.**—I am much indebted to "T. C., Bristol," "Elag," and "Milverton" for their answers to my question on Torricelli's Theorem. Working for the advanced examination in theoretical mechanics, and having no one to coach me, I sometimes get stuck. Can you give me a simple formula for finding the centre of pressure? There is nothing of the kind in Twisden's "Mechanics." Apply the formula to the following: On the vertical wall of a reservoir, a circle is described with its centre on the surface of the water; find the centre of fluid pressure of the part under water.—S. FORD.

[61708.]—**Superphosphate.** — What strength of sulphuric acid is used in dissolving ground phosphates? In what proportions are they mixed to make a superphos. of 30 per cent. Any simple method by which the solubility of same could be tested?—S.

[61709.]—**Medical Electricity.**—Many thanks to W. Holder and E. Conry for replies to inquiry respecting lining for accumulators. I shall be glad if any reader can suggest a means of applying current from accumulators for rheumatism. I have about 20 cells = 40 volts, and would be glad if the current of all or part can be utilised for this purpose. I use the cells for house lighting, so that they are generally charged every day at this time of year.—VOLT.

[61710.]—**Speed Indicator.** — Would one of our Brighton railway correspondents explain working of speed indicators as fixed to Gladstone class, and whether they are of much use?—G. AND S.W.RY. FITTER.

[61711.] —**Solar Microscope and Gregorian Telescope.**—I have a microscope, similar exactly to picture in "Popular Educator" (Vol. V. p. 249, fig. 7). The text states it to be copied from an old work published in Amsterdam in 1776, and alludes to it as a rare and obsolete instrument. Could any correspondent conversant with these matters give me some information as to the use and value of the instrument? It is very well made, and is accompanied by a number of small eyepieces covered with brass caps and marked 1, 2, 3, 4, and a number of other paraphernalia, including slips of ivory, each containing five small glass discs, with objects thereon. I have also a Gregorian telescope, 18in. long, shows the moon apparently 20 times length of usual image, markings and shadows shown very distinct. What power would this be called? Could I purchase higher-power eyepieces ready made, or should they be made specially for the instrument? What powers are necessary to show Saturn's rings, snow cap on Mars, &c., and what would such eyepieces probably cost?—SLANDINGO.

[61712.]—**Chloride of Silver Battery.**—Will Mr. Conry, or some other reader, kindly give me particulars, as to Skrivanoff's chloride of silver battery—full instructions, enabling me to make one? Also give particulars as to the solution and method of renewal when exhausted? Are they of use in house lighting?—INVICTA.

[61713.]—**Ferrules.**—Wanted, instructions to enable me to make stampings out of brass sheet to form ferrules, &c. What kind of metal is used, and what precautions are to be taken to prevent the cracking of metal? How are the different diameters in ornamental tubes allowed for? How are screws punched on in pepper-box caps?—INVICTA.

[61714.]—**Steam Ways and Ports.**—To "T. C., BRISTOL."—Can you oblige me with size of steam ways and ports of single-cylinder launch engine, 1in. bore, 1½in. stroke, and is cast brass as good as spun or riveted for a small dome to stand about 20lb. pressure?—VALVE.

[61715.]—**Faulty Organ.** —Would some of your correspondents kindly furnish me with the following information? There is an organ at our place that is rather annoying. The lowest D of the row of keys (when pressed down) makes a rough, reedy, clattering noise, whatever stop is out. I think that it is something got loose some way between the foot of the pipe and the pallet, or else the slider. It sounds bad and rough. I shall be glad if I could know some way of remedying it. Also, belonging to the same organ, there are two keys (both are D sharp) which cipher very much, and however much the keys are shaken up and down it makes no difference—it does not stop it. I shall be very glad if some one of your readers, who understand the organ thoroughly, will tell me what the causes are, and how to remedy these faults?—CONSTANT READER.

[61716.]—**Electric Light.** — To light four incandescent lamps of 10 or 15c.p. for five hours nightly, what battery is best for the purpose, and what number of cells will be required to maintain the light efficiently for 10c.p. lamps, and what for 15c.p. lamps?—SARDONYX.

[61717.]—**Chemical Precipitate.**—I dissolve 50 grains of nitrate of silver and 10 grains of sulphate of copper in 6oz. of distilled water. I then add strong ammonia until the liquid is of a deep blue colour and quite clear. In a short time a black powder is precipitated. How can I prevent this, or how can I redissolve it?—J. B. BLEW.

[61718.]—**The Leeds Parish Church Organ.**—Would Mr. Audsley oblige by giving the present specification of this organ? I have a cutting from the ENGLISH MECHANIC giving a specification, but this must be of the organ as it existed before the rebuilding a few years ago, as it does not show a manual 32ft. stop. Can Mr. Audsley say if the grand Schulze diapason, to which he refers, is still in its original condition? I certainly did not hear, or, at least, recognize it, when I was there some time subsequent to the rebuilding, and I was told that the present condition of the organ was not generally considered satisfactory by musicians who knew the instrument before the rebuilding.—SANDERSON CORPUS.

[61719.]—**Straightening Wire.**—Can any reader describe the best way to straighten half-annealed Bessemer steel wire? I remember noticing, whilst walking through a large wire mill some years ago, a small apparatus revolving at a very high speed, through which, by means of hollow spindles at each end, wire was easily drawn by a boy and came out perfectly straight. I should now much like to know the internal arrangement of this kind of machine, and whether it has to be adjusted for different conditions and gauges of wire.—H. C. C.

[61720.]—**Photo. Exposures.**—In Burton's Tables, there are good guides as to relative exposures for months and hours of the day. Will someone supplement same by saying probable increase caused by sun being obscured and by a dull day? Thus, by Table iii. we are told if a lens requires an exposure of 1s. at 12 o'clock in June, it will in February require 2s.; this for good sunshiny day. What number will these require to be multiplied by if (*a*) a cloudy day, (*b*) if a dull day?—J. R., Plymouth.

[61721.]—**Quick Writing of Notes.** — Some time since, but I do not know when, I saw an advertisement in "Ours" of a system of abreviated longhand in distinction to shorthand. Can anyone tell me anything of same, or such a system, or of any pamphlet, &c., thereon?—J. R., Plymouth.

[61722.]—**Photography.**—I have seen a print of a distant view, and was struck with its beauty, the object, though nearly half a mile off, being exceptionally well defined, whilst the foreground was distinct and clear—in fact, everything from a yard to half a mile seems to be perfectly in focus. What make of lens is this that possesses such penetrating, as well as defining, power? Is it possible to do such work as this with the ½-plate R.R. Optimus lens? If so, a few hints will oblige—A NOVICE.

[61723.]—**Moulding Rubber Goods.** — I am desirous of making an article of soft rubber, and should be obliged to any reader who would inform me as fully as possible how such articles as tobacco pouches, &c., are made. If any publication is issued which would meet my wants, kindly name.—JOSHA.

[61724.]—**Telephonic.**—Could any of your readers inform me which is the best form of transmitter for speaking telephones?—ZIRCONIUM.

[61725.]—**Photographic Query.**—I have taken a few photographs (8 secs. with four stop), on Derwent plates (extra rapid), of a house, and when developed and fixed are very thin. I use Edwards' developer. Could any of your readers tell me what is probably the cause of it?—SPHYNX.

[61726.]—**Cotton-Seed Oil.**— In last week's issue, under "Exercises in Technical Analysis," referring to a recent decision in Glasgow, I find: "This decision declares olive oil to be an article of food, and the addition of cotton-seed oil an offence under the Food and Drugs Act." As an old subscriber, will you allow me to ask "our" Mr Allen if there is any reason why cotton-seed oil should not be as much an article of food as olive oil? I have used it, and I know many others who are constantly using it for cooking purposes, without (so far as I know) any injurious effects. Should cotton seed be any more injurious than linseed? I have used refined cotton-seed oil which, for flavour and richness, I have thought equal to the best olive oil, at a much less cost than olive, and I think its recognition as a food would be another economical addition to our food resources.—PUBLICOLA.

[61727.]—**Locos.—L. and S.W.**—Will "V. J. B.," or any other correspondent, give me particulars as to date, builder's name, weight in working order, and type of the L. and S.W. locos. Gaul, Dane, Castleman, and Nos. 470 and 521 (no names)? Also G.E.R. loco. 659, and M.R. locos. 1258 and 1692, and L.B. and S.C. locos. Balham, Buckhurst, Clapham?—REINDEER.

[61728.]—**Motor for Small Organ.**—Will any of "ours" kindly help me out of a difficulty? I am making a small water motor, with a cylinder 1½ bore by 5 stroke, and cannot make the valve act. When the piston has moved the valve (a four-way tap) half way the motor stops. I have tried all manner of ways, with springs, &c., but cannot succeed. I have seen some of these machines at work (e.g., Crystal Palace), and the valves seem to work themselves immediately they are touched by the rod. Can anyone explain the action of these valves? A sketch will oblige—PRESSURE.

[61729.]—**Estimating.**—Would any of your numerous readers kindly inform me of a good work treating on the estimating of builder's work?—YOUNG BUILDER.

[The best work of the kind appeared in the leading architectural paper, the *Building News*, and has been republished in book form by B. T. Batsford, 52, High Holborn.—ED. "E. M."]

[61730.] — **Conservation of Energy.** — Would somebody kindly inform me what fraction of the energy contained in coal is made use of by the finest constructed engine? Also, how much of the energy contained in his food is made use of by man?—E. G. M.

[61731.]—**Injector.**—Can any of "ours" give me any information how to make the above work at high pressure, say 60 to 80? I can only get it to work at 35 to 45, which is too low.—G. ROE.

[61732.]—**Models of Buildings.**—I am making a model building of pasteboard, and I want to coat the outside of it with some substance that will remain soft while I mark it to resemble cut stone. Could you kindly give me a recipe how to make such a substance?—J. F., Dublin.

[61733.]—**Oils and Tallow.**—Will someone oblige by giving recipe for detecting vegetable matter, say seed oils, when mixed with animal oils, or with tallow?—TESTER.

[61734.]—**Iron v. Steel.**—(See p. 521, letter 26816, 3rd column, last paragraph). Questions which Mr. J. G. Shepherd will perhaps kindly answer: (1) What is the melting point, F. or C., of wrought iron, malleable iron, and soft cast steel? (2) Does Mr. S. mean "malleable iron" (i.e., cast iron rendered malleable), or does he refer to wrought iron? (3) When wrought (in that sense malleable) iron is used, is not a special melting furnace required? (4) Does Mr. Shepherd mean that the aluminium is added before or after the melting? (5) If added before the melting, would the aluminium not be alumina if a blast used before the iron melts? (6) Must not the aluminium be added before the iron is melted, and how? (7) Would not the Mitis process be more correctly described as making the alloy fusible at a lower heat, so as to have spare heat during the process of pouring?—R. S. T.

[61735.]—**Screw-cutting.**—I have two screws to cut in steel, and shall be glad of a little instruction. One is a buttress screw 12in. long, 1in. diam., ⅜in. pitch, and the threads a quarter deep; the other is a round thread, 12in. long, 1in. diam., ⅜in. pitch; threads, ⅜in. broad and ¼in. deep. I am a new hand at screws, so shall be glad of elementary instruction.—ANXIOUS.

[61736.]—**Harp.**—Is there any published work on the practical construction of the harp?—J. E. D.

[61737.]—**Size of Steam Boilers.**—Wanted, a rule to find the size of boilers that will work given steam engines.—S. CRABTREE.

[61738.]—**Shirt Buttons.** — Would one of "ours" kindly explain how the ordinary mother-of-pearl shirt buttons are made? They appear to be turned; but unless this can be done by machinery automatically, it seems impossible that they can be made at such a low price as they are sold at.—B. H.

[61739.]—**Sand Figures.**—I have been experimenting with Chladni's sand plates, and have been able to obtain several complicated and beautiful sand figures; but completely break down over the production of the 30 odd ones figured in Tyndall's lectures on sound. I should be glad if any correspondents who have investigated this subject would suggest the method of their production, or any book on the subject. I may say that I have got several figures which are not shown in Tyndall's work; but they are poor affairs beside the drawings delineated there.—S. J.

[61740.]—**Frankenstein.** — Can any correspondent inform me whether any modern edition of "Frankenstein" has been published, and, if so, where it is obtainable? I have always understood it was written by Mrs. Shelley in a few hours for a wager; but I have never succeeded in securing a copy of it.—DOCTOR MEDICINÆ.

[61741.]—**Brake Trial at Ipswich.**—I read in a local paper that the Great Eastern Railway have been experimenting last week with a new brake fitted to six coal waggons. Can any reader tell me what the new brake is? It is without doubt a great stride in the brake question that coal waggons should be supplied with brakes that fulfil the Board of Trade conditions. What a change from the time when such brakes were objected to on passenger trains!—RY. STUDENT.

[61742.]—**Railway Signals.**—Has any further step been taken to get railway companies to adopt one code of signal lights, so far, at least, as refers to green or white all-right lights?—INQUIRER.

[61743.]—**Winking and Blinking.**—Can any of your medical or other readers say the cause and cure for this in a boy 14, who has had it for some years?—OPHTHALMIC.

[61744.]—**Emery Wheel.**—What grain emery wheel should I require for taking the stone marks out from razors and small scissors after grinding? Can the same "colour" (polish) be given to the article as with a wooden wheel used in the ordinary way? I am now using a mahogany wheel with No. 80 hole emery and oil.—SELIM.

[61745.]—**Mechanics.** — Would any of our correspondents kindly give an amateur a rough sketch of the feed motion to work the cross slide of a planing machine?—NOVICE.

[61746.]—"**The Last Quarrel.**"—Can any reader give the author of a poem which I am told is called "The Last Quarrel"? The scene is laid in the Isle of Wight, and is between a man and his wife about a letter; the man crosses the Solent and is lost.—ARQUES.

[61747.]—**Moss.**—How is it dried and how treated to give it the fresh green colour it has when seen in the greengrocer's shops?—W. H. B.

[61748.]—**Electric Light.**—Can any reader help me? I want to light my shop by electric light. I have a gas-engine (2-man-power Bischopp). Could I make a dynamo that this would drive, and how many incandescent lamps would it light? I am now using four gas burners, which light it well, as it is only a small shop; but as it is a cutler's, the cutlery gets in such a state from the moisture which condenses on the window. Distance from engine is about 30ft. I am expert with my tools, and could manage to work up castings, &c.—SELIM.

[61749.]—**Lathe Matters.**—Will Mr. Evans, Dr. Edmunds, or someone kindly assist an amateur? I am making an eccentric chuck and cutter frame. The main screw of my slide-rest has eight threads to the inch. Ought I to (1st) make the traversing screw of chuck and cutter with same number of threads? 2nd. Should I, in that case, divide the micrometer on them into 8 or 10 divisions? or (3rd) should I make the screws with 10 threads and divide the micrometer into 10 divisions? I see in Holtzapffel. Vol. V., he makes all his screws 10 to the inch; but then his slide-rest main screw has the same number; hence my difficulty.—E. H. DOWSON.

[61750.]—**The Exact Time.**—Can any of our readers inform me of any source of approximately exact time which is independent of the current from Greenwich? Big Ben is probably generally correct, but cannot be read by sight within half a minute for want of a second hand, which Lord Grimthorpe writes me it would be impossible to add to the clock. After the snowstorm all London was, for want of such a clock, without any exact time for more than a month, whilst the connection with Greenwich was destroyed.—MONTMARTRE.

[61751.]—**Exact Measures.**—Whilst waiting for the fall of the 1 o'clock ball at the Observatory, Greenwich, during the break-down of the electric wires, I one day occupied a few spare minutes in testing the metallic tape measure which I carry in my pocket against the Standard measures of length inserted for the use of the public in the wall of the Observatory, and was greatly surprised to find the tape measure short of the Standard length by nearly an eighth in the foot and over three-sixteenths in the yard. What "standard" do makers use?—MONTMARTRE.

[61752.]—**Dirty Ceiling.**—The ceiling of our best room seems to have been finished with a coating of plaster-of-Paris. Both the moulding and centre-flowers when washed are of a dull grey colour instead of a clean white, and how ever many times we whitewash them we cannot get them to take an even coat, but they always appear to be greasy and streaky. What should be done to kill or overcome this nuisance?—ANNOYED HOUSEWIFE.

[61753.]—**Sympathetic Vibrations of Jet—The Graphophone.**—The "E. M.," Sept. 3rd, 1886, contained an abstract of a paper with the above heading, read by Mr. C. A. Bell before the Royal Society. Owing to absence from home, I have been unable myself to repeat these truly beautiful experiments; but some time ago, I sent the abstract with copies of the drawings to a scientific friend of mine, who was successful in all except the last two, Figs. 6 and 7. No. 6, he says, puzzles him. The drawing represents a water jet under about 15 decimètres pressure. The only result he could get was a great noise of pattering on the diaphragm. How is the electric connection made in Fig. 7? All experiments with jets are so beautiful that probably many readers of the "E. M." have repeated those given in the abstract, and any further light on the subject would, I am sure, be interesting to many. The drawing Fig. 8 is meant to explain Fig. 7, but I fail to understand it. I hope some of your scientific contributors will be so good as to make the matter clear to me, and, I may add, to many others also.—AN OLD SUBSCRIBER.

[61754.]—**Crystals in Leaf.**—I have lately been mounting transverse sections of leaf of Prunus laurocerasus (cherry laurel), and noticed in the spongiform layer of cells numbers of colourless rhomboid plates. Can any of our microscopical readers say what these are likely to be, and whether they have been previously noticed? The sections were floated off into water when cut, cleaned in oil of cloves, and mounted in balsam (power 350 dia.). I thought it might be the glucoside amygdaline, but understood that in P. lauro-cerasus it was amorphous, and would it not decompose with emulsion and water into HCN and glucose? Another suggestion is that they are the "crystalloids" of Nägeli.—REYMOND.

[61755.] — **Medical Battery.** — Will any reader inform me how to connect up a 36-cell medical battery, having two dial collectors, so as to commence at either end of battery? Each dial collector is numbered from 0 to 18 inclusive. The zinc of the first cell was formerly connected to 0. Wish to dispense with double wires, if possible.—CIRCUIT.

[61756.]—**Lame Jackdaw.**—I have a tame jackdaw, and since the cold weather came in he has got very lame on one foot. It has swollen, and on handling seems heated, and pains him on touching it. I showed him to a bird-fancier, who said he had got chilblains, and advised me to bathe in warm water and then oil. This I have done several times, but it is no better. Any hints will oblige, as I do not like to see him limping about.—J. I. S.

[61757.]—**Legal—"Back Letters."**—A rich brother long settled in England for some time assisted me with a yearly gift of money, and I then granted him a bill payable on presentation for the total amount. He thereupon gave me a "back letter," explaining the nature of the transaction to be only in order to enable him, in the event of my death, to rank on my estate, but that even then the bill would not be presented unless he or his family actually stood in need of the money. I understand that a back-letter given in Scotland by a domiciled Scotsman is a legal obligation. Would one granted in England by a person domiciled there be so also? I have heard that back letters were unusual in the latter country.—W. B.

[61758.]—**Legal.**—Owing to the agricultural depression, a rector, being without tenants, is compelled to farm his own glebe land of some 500 acres. In the event of the rector dying, or giving up the living, would his successor be liable to pay him for the ordinary farm valuations, acts of husbandry, root crops, &c., in the same way as is done between ingoing and outgoing tenants of a farm, or would the retiring rector (or, if dead, his executors) be allowed a certain period to retain the farm after the arrival of the new rector, so as to gather in and dispose of all the existing crops, straw, hay, &c., in the event of the new rector declining, or not being liable, to pay for them?—E. A. LITTON.

[61759.]—**Oxygen Gas.**—Can any reader inform me at what pressure oxygen gas may be liquefied at the ordinary temperature of the atmosphere? Oxygen gas has been liquefied by means of pressure and great cold; but I wish to ascertain if pressure alone has yet been able to liquefy it, and, if so, how many atmospheres is that pressure calculated to be; or I would be glad to know the greatest pressure to which oxygen has been subjected without any change in its gaseous state being observed?—D. W. J. R.

[61760.]—**Fan.**—As I have an 8in. fan which I am going to use with a small forge (sometimes with a large blowpipe), I would ask the writer of the articles on Forge, &c., to indicate a good general arrangement for placing the driving pulleys and fan. My fan has a 2in. hole with flange. How much taper shall I want on the pipe connecting it with the tue iron? and which is the best mode of connecting to the latter? Can I purchase a suitable connecting taper pipe, or how shall I have to make a pattern for one in this case?—J. ADAMS.

[61761.]—**Table of Sizes.**—Could any brother reader assist me with the following? How much travel per inch of diameter ought the inside calipers or gauge have so as to insure a good driving fit; for instance, the crank-pin of the screw-steamer *Arizona* is 23in. in diameter, and the crank-pin hole is 18in. deep, what travel would be allowed to insure a good tight fit? I should be glad of any information on this subject, or any reference as to where it can be found. I may add I have a table of sizes from 1in. up to 100in. dia. for working fits, and I have found from experience that 1-16in. per inch of diameter is a good rule to work from, but I have very little experience of driving fits.—TURNER.

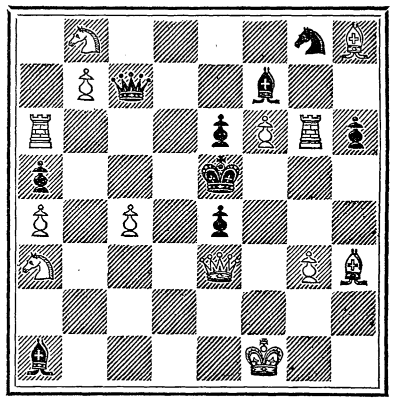
[61762.] — **G. and S.W. Ry. Locos.** — Would "Engine-Fitter," or some other reader, give a description of the way in which these engines are reversed? I have noticed on the express locos., that instead of the ordinary reversing lever a horizontal cylinder is situated on the foot-plate at the driver's right hand, which, when steam is admitted to its piston in some way moves the links. By what mechanism is this effected? Give dimensions of the old outside cylinder single engines, and say by whom they were built. I sometimes see them used for passenger trains.—AMATEUR.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXXI.—BY A. BOLUS.

Black.



White. [13 + 9

White to play and mate in two moves.

SOLUTION TO 1,029.

White.	*Black.*
1. R-Q Kt 7.	1. Q-Kt sq (*a*).
2. Q-B 4 (ch).	2. P takes Q or Kt.
3. Kt or R mates.	
	(*a*) 1. Q takes Kt (*b*).
2. R takes P, &c.	
	(*b*) 1. P Queens (*c*).
2. Q-Q B 2, &c.	
	(*c*) 1. P-K 7 (*d*).
2. Q-Kt 3, &c.	
	(*d*) 1. B-K 7 (*e*).
2. Q takes P (ch), &c.	
	(*e*) 1. Kt-Kt 3 (*f*).
2. R takes Kt (dis. ch), &c.	
	(*f*) 1. P-R 4.
2. Q-B 4 (ch), &c.	

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,029, by Major (grand problem—one of the finest seen for a long while), V. S. Pochin (several important variations omitted), H. Hosey-Davis (very good key and some pretty play; too many duals), Black Pawn (dual mates dreadfully numerous). Link, A. Bolus (many duals); to 1 028, by Hensing, T. H. Billington, Avon, and Country Boy.

V. S. POCHIN.—You are wrong in your second solution of 1,029. If 1. $\frac{\text{B takes P}}{\text{Q takes B (ch)}}$, so that R cannot play to K B 4 on the second move, as you propose. You are right as to your solution of 1,027; correction made. We will refer to the other problem you allude to.

A. DEAN, F. KRASSER, AND A BEGINNER.—If in 1,029, 1. $\frac{\text{R-K 7}}{\text{Q takes Kt}}$, 2. $\frac{\text{Q-K B 4 (ch)}}{\text{K takes Q}}$, and there is no mate. If 2. $\frac{\text{B takes P}}{\text{Q-Q B 3}}$, and again White cannot mate next move. If 2. $\frac{\text{R takes Q}}{\text{K-Q 5}}$, and K escapes at B 4.

W. HEWSON-KILBEE.—If 1. $\frac{\text{R-Q 7}}{\text{Q takes Kt}}$, and how then?

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

*** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.

The following are the initials, &c., of letters to hand up to Wednesday evening, Feb. 16, and unacknowledged elsewhere :—

MEDICAL BATTERY CO.—Gregory Wright.—R. Lloyd and Co.—Capt. Smithwick.—Victor Nielsen.—W. K. Fulleylove.—E. W. W.—Doubtful.—J. N. C.—Goolwa.—Dyer.—H. H.—C. P. Bartholomew.—Geo. Button.—Arcadian.—T. G. Elger.—J. C. T.—T. F. S. T.—A Fellow of the Royal Astronomical Society.—W. J. S. Barber-Starkey.—S. P.—New Reader.—Beginner.—The Writer of Letter signed "Another Fellow of the Royal Astronomical Society."—Picklock.—Optician.—W. A. Barber.—Joiner.—Spectator.—E. M.

BEGINNER. (You must test it, or get it tested. No one can tell you the candle-power of an incandescent lamp when all the data you give are 2in. in diameter and 3½in. long. See indices or recent back numbers. We believe we answered you on p. 488.)—H. S. (Yes, arc lamps have been fitted to magic-lanterns. See catalogues of dealers, and such books as "Ganot's Physics.")—TYRO, A NEW SUBSCRIBER. (Black for stopping out in magic-lantern slides can be made by dissolving asphaltum in turpentine, and using the solution as a medium for grinding lampblack. If properly ground, and a little mastic varnish added, the result is a fine black, quite impervious to the strongest light. As to lenses, see p. 484 this volume, and on painting slides, if you cannot refer to back volumes, procure the guide by "Sable," published by Mr. Hughes, of Mortimer-road, Kingsland, N.)—THOMAS SMITH. (Medical queries are answered in the *Weekly Times and Echo.*)—TEMPUS. (No. 924 being out of print, another number has been sent containing the information. Try Messrs. Cotterill, Rodney-street, Liverpool.)—SOLDERING IRON. (We do not think it worth "working out." There is no difficulty in tinning a copper-bit, nor in using it when tinned.)—F. H. (At any of the large wire-workers or dealers in such materials. 2. By adding oil or wax to it. Does it not strike you that the candles cannot be made of paraffin? Most likely they are stearin.)—MARINE. (To become a marine engineer you must have been at sea at least one year, and have been employed in the engine-room. That is, assuming you have served three years at least in shops where engines are made. Otherwise four years' service is required. As you have not had any technical training, we imagine you will find great difficulty in obtaining a berth.) — E. P. (Safety paraffin lamps would naturally be the subjects of patents. We are not aware that any prize has been offered for one; but a prize has been offered for a miners' safety-lamp that will comply with certain conditions.)—R. SMITH. (Nos. 1108, 1130, 1132, contain the notes on heating water rapidly.)—M.SC. LOND. (Shred the light-coloured bottle-rubber fine, and put it into bisulphide of carbon.)—MEDIÆVAL. (Brazing has been explained over and over again. The parts to be joined are thoroughly cleaned and covered with borax and brass clippings or "spelter." They are tied together with iron wire, and heated until the brass runs into the joint.)—A WORKING MECHANIC. (A small hole is left in the lid, and a little piece of tin plate underneath, to prevent the solder running through. The tins are then placed in a bath of brine or chloride of calcium, and when all the air has been driven out by steam, the hole is closed with a drop of solder.)—G. M. (They are salted and smoked, or are supposed to be; but too often they are merely dipped in a preparation of pyroligneous acid. 2. If you cannot refer to back volumes, see Heather's "Surveying and Astronomical Instruments." 3. If you take the iron continually it will prove injurious; but how comes the water to have so much rust in it if the supply is constant?)—DICK. (A "perpendicular" line is one drawn at right angles to any given line; a "vertical" line is one that is upright or at right angles to the horizon.)—N. R. (No book specially devoted to the subject. There are articles in cyclopædias and in our back volumes, and in Hofmann's "Paper Manufacture"; but that costs three guineas and a half.)—G. W. L. (Probably a derivative of Rangoon petroleum. Where do you find any mention of it?)—A. H. G., Bristol. (You will find many receipts by looking through back volumes; but if you refer to Cooley's Dictionary, or such a work as "Enquire Within," you will have a choice of a considerable variety of more or less value.)—R. DRAKE. (There is no work on such a subject, nor is it easy to understand how there could be, for the operations required are merely the modified application of the usual processes of the workshop. Methods of hardening steel have been explained over and over again; but it is not easy to teach the use of the file or to impart skill by mere verbal description.)—SUFFOLK. (You must have suitable steel and much practice. See pp. 152, 174, 196, Vol. XLI.; or you will perhaps find the "secret" in No. 741, p. 320, or No. 709, p. 180. There is plenty of information about working mill bills in back volumes; but for definite instructions the kind of steel must be known, as Mushet's requires different treatment to ordinary tool steel.)—L. V. (You can make all sorts of rockwork for aquariums by covering objects with Portland cement; but why not use natural rock and shells? Get the plants to grow well before putting in the fish.)—CUTTER. (The usual tools employed for turning steel. 2. Haydon's cutter-bar, with directions for using it, was illustrated so recently as No. 1071. See also Nos. 1060, 783, 784, and the indices generally. You can get an illustrated circular from the Britannia Company.)—C. TRATHEN. (We do not know what it is you refer to. There have been several articles on triple expansion engines in our columns, and the method of getting the best diameters for the respective cylinders is obviously a matter of calculation.)—CAPTAIN J. (The query you put has actually been dealt with in recent numbers. See p. 430. In the summer the sun is higher up, and this country catches his rays more directly.)—S. G. (Clean with sand, pickle with acid, rinse with hot-water, immerse in a bath of melted grease, and then dip in the molten tin. If you mention what sized articles you wish to tin, more definite directions can be given.)—PILULE. (Directions for coating pills with sugar in No. 966, p. 94. The percentage allowed varies from 30 to 50; but such queries are of little interest to readers.)—LEARNER. (For so small a number of copies it is not worth while using the lithographic process, especially as you must have a press. There is a book, and you will find all necessary instructions in Richmond's "Grammar of Lithography." Wyman and Sons, Great Queen-street, Lincoln's Inn Fields.)—ZINCO. (We are in doubt as to which process you mean; but all have been described in back volumes. See p. 155, No. 1074, and the index to Vol. XXVII. If a rubber stamp will not do, why not print from a block?)—CHARLES MURFITT. (If you are as you say, "An Old Subscriber," what have you done with your back volumes? We were under the impression that nearly every conceivable method of fitting up electric bells had been described in our columns; but you want elementary instruction. If you cannot see back volumes, procure the little pamphlet from Gent and Co., Leicester, advertised on the front page.)—RUSTIC. (It is hotter at the bottom, and consequently rises to the surface, where it becomes cooler.)—T. K. W. (Most likely by boiling both, when they become soft. Then by expanding the hole and squeezing the piece which has to be inserted, the "puzzle" is solved. That is how most puzzles of the kind are done.)—COOPER'S HILL. (Every member receives a copy of any Blue-book or other matter ordered by the House to be printed, and the public can purchase anything of the kind at a price fixed by the cost of production. 2. London, Southwark, and Waterloo were built by Sir John Rennie, assisted by his sons in some cases; Blackfriars, by Joseph Cubitt; Westminster, by T. Page; Lambeth suspension, P. W. Barlow; Chelsea suspension, G. G. Page. Vauxhall was begun by Sir John Rennie and completed by James Walker. 3. Nothing more has been heard since the finding of the Court; but there is no doubt that she had an enormous hole in the side.)—H. T. (Celluloid is polished in much the same way as ivory, with fine glass-paper and with whiting and spirits or water.)—FLEUR-DE-LIS. (Which concertina do you mean? However, the scheme of tuning has been frequently given, and the rest is practice—learning to distinguish the beats.)— ARTHUR. (The information asked for *has been* found generally acceptable to a large number of our readers, as you will find if you refer to the indices. Look through the back numbers of this volume, or say what sized coil you wish to make, and then we may possibly be able to indicate in which back number you will find instructions.)—W. R. (Yes, the dry plate has "almost entirely superseded" the old process. There may, in some special conditions, be an advantage in the wet process; but we imagine it would take a great deal of discovering.)—J. (A physician, certainly. Your medical man will know of a specialist. 2. Medical advice should be sought. Beyond that, exercise in open air, no suppers, and the usual rules for leading a healthy life.)—T. (A Mustel organ is a high-class harmonium, and if you do not recollect seeing any description in our pages, it is because you have not looked for it. You will find a sectional diagram of the instrument in No. 577, and a good deal about that and others in subsequent numbers. See p. 425, Vol. XLII., and the index of that volume.)—READER. (Your question has been answered many times, and can be answered by any teacher of a science class. Replies could only be gratuitous advertisements, and the selections might be invidious, as several publishers issue suitable works—*e.g.*, Longmans, Crosby Lockwood and Co., Macmillan, Cassell, &c.)—R. (Any good book on the subject. See publishers' lists.)—ELECTRA. (Perhaps plaster of Paris will do, or marine glue. 2. Any of the bichromate arrangements, the chloride of silver, or sulphate of mercury cells. See indices for "portable batteries," however, as there are several useful modifications.)—W. E. M. (See p. 418, reply 61291, and many recipes in back volumes.)—R. M. (Impossible to say without analysis; but a first-class tooth paste is made of 8oz. prepared coral, 4oz. cuttlebone, 2oz. mastic, ½oz. cochineal, ¾lb. of honey, a fluid drachm of essence of ambergris, and ½ fluid drachm of oil of cloves. Dissolve in a fluid ounce of rectified spirit.)—PUNCH. (Mushroom-growing indoors and in the open air has been frequently described in back volumes. Procure Mr. Wright's book on the subject from the *Journal of Horticulture* office, 171, Fleet-street, E.C., price one shilling.)—IOTA. (We had had enough of the subject. 2. Yes, as a letter.)—P. WARD. (We cannot make exceptions to the rule; if we do, we are blamed for unfairness.)—E. CONRY. (We are obliged by your kind offices; but your replies reach us so late that we are sometimes unable to use them. This week we have to hold all over.)

USEFUL AND SCIENTIFIC NOTES.

A New Dentifrice.—The *Gazette Hebdomadaire* contains an article by M. Paul Vigier on the "Use of Steatite as a Tooth Powder." Many years back M. Vigier discovered that the addition of powdered talc to water prevented the deposit of calcareous salts in boilers. Applying this fact to dental therapeutics, M. Vigier has devised a new dentifrice, which, he says, prevents the formation of tartar. The formula is as follows:—Powdered steatite, 60 grammes; desiccated alum or cream of tartar, 5 grammes; powdered cochineal, 10 grammes; essence of peppermint, 20 drops. Any other perfume may of course be substituted.

New Books of 1886—The number of new books published in the year just closed was 3,984, and of new editions 1,226—a total of 5,210. This is a falling-off of more than 400 from the publications of the year 1885, which were 5,640 in number. Messrs. Sampson Low, Marston, Searle, and Rivington, to whom we are indebted for these figures, publish, as is their custom, an analytical table of the books published during the year. The table is divided into fourteen classes, and the numbers of each are as follows:—Theology, including sermons, 752; educational, 572; juvenile works and tales, 445; novels, 969; law and kindred subjects, 33; political and social economy, trade and commerce, 246; art, science, and illustrated works, 178; voyages and travels, 221; history and biography, 350; poetry and the drama, 93; year books and serials, 294; medicine and surgery, 171; belles-lettres, essays, and monographs, 479; and miscellaneous, 407. From the table of publications issued every month, it appears that January was the weakest, producing only 205 books. The number rose, with considerable variations, to 445, or more than double, in June, fell continuously to 258 in September, rose to 602 and 642 in October and November, and finally reached 852 in December. Most of the fourteen heads show a decrease. Novels increased from 455 to 755.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and CO., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or 2½d. each, post free from the office (except index numbers, which are 3d. each, or post free, 3½d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free 2½d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, 3½d. Cases for binding, 1s. 6d. each.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

CHARGES FOR ADVERTISING.

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

The English Mechanic

AND WORLD OF SCIENCE AND ART.

FRIDAY, FEBRUARY 25, 1887.

THE BIRTH OF MATTER.

THE old idea of the alchemists, embodied in their views as to the transmutation of metals, has never been altogether excluded from the "scientific use of the imagination," and even the textbooks which give a list of the elementary bodies also contain the intimation that for all we know to the contrary those forms of matter which we call elements may possibly be capable of analysis into one simple substance, if only we had some more powerful means of chemical analysis than we possess at present. We recognise some seventy forms of matter which we are unable to split up into other forms, and which we can mechanically divide to an extent which indicates only further divisibility beyond our powers of vision, and almost beyond our powers of conception. Matter qua matter is indestructible, so far as we know, and therefore when we speak of the birth of matter we refer to its form in its earliest condition—the next stage to Mr. Crookes's protyle, the birth of the elements. It will be remembered (see p. 29 ante) that, at the meeting of the British Association last autumn Mr. W. Crookes, F.R.S., delivered, as president, one of the most remarkable addresses ever heard in the section devoted to chemistry. It was an attempt, made with knowledge and with the scientific use of the imagination, to describe what may have been the genesis of the elements; and, last Friday, before a distinguished audience at the Royal Institution, Mr. Crookes introduced a series of what it is the fashion to call "brilliant experiments," with the object of showing that a belief held by such men as Brodie, Clerk-Maxwell, Dalton, Dumas, Graham, and others equally distinguished, is based upon a solid groundwork of fact. Chemists, as a body, are inclined to the belief that the elements are compounds of simpler substances, perhaps of one; but there has hitherto been little evidence of the truth of the theory, and it has been simply regarded as an hypothesis to be cherished and to be worked with when unexpected results are obtained in the course of an investigation. At the beginning of the present decade we heard a good deal about the primal element hydrogen and the dissociation of carbon, based upon crude observations with the spectroscope; but Mr. Crookes had already obtained some rather inexplicable results with his rare media and his radiant matter, and following on the lines or on those opened out by his researches he was able to give something more than the old reasons for believing that the elements, or some of them at least, are really compound. In concluding a lecture delivered before the British Association at Sheffield in 1879, he said that "we have actually touched the borderland where matter and energy seem to merge into one another, the shadowy realm between known and unknown, which for me has always had peculiar temptations. I venture to think that the greatest scientific problems of the future will find their solution in this borderland, and even beyond; here, it seems to me, lie ultimate realities, subtle, far-reaching, wonderful." At the last meeting of the British Association, at the conclusion of his long address, he said: "Summing up all the considerations, we cannot, indeed, venture to assert positively that our so-called elements have been evolved from one primordial matter; but we may contend that the balance of evidence fairly weighs in favour of this speculation." The more deeply we dive into the mysteries of nature, the stronger becomes the evidence for evolution, not merely in one branch, but in all, even in the very elements themselves. It is not easy to perform a number of "brilliant experiments" before a sectional meeting of the British Association; but in the theatre of the Royal Institution Mr. Crookes was able to show to a critical audience the facts on which he based his far-reaching hypothesis. The steps by which the present position has been reached may be traced by referring to the records of the researches of Mr. Crookes in Vol. XXVIII. p. 383, on an ultra-gaseous state of matter; in Vol. XXIX. p. 512, molecular physics in high vacua; and p. 639, radiant matter. On Friday last he was able to boldly lecture on the "genesis of the elements," and to show that there was reason to suspect that he had broken up the "element" yttrium into perhaps six new "elements." He produced a glass tube containing air of only the fifty-millionth of an atmosphere in density, and holding within a capacity of about five cubic centimètres (little more than ·3 cubic inch) one hundred million million molecules. The yttrium broken up or dissociated in an atmosphere of about one-millionth by means of the electric current, and examined by the microscope, produces fine examples of the phosphorescent glows to which Mr. Crookes has introduced us, and pushing the examination further, in still higher vacua, appearances are obtained which lead to the conclusion that the yttrium has been formed by the combination of six simpler substances, possibly derived direct from the original protyle, and caused by varying states of electricity, or what we call electricity, and heat to shape themselves into the "element" yttrium. The "genesis of the elements" sketched out by Mr. Crookes in his famous paper would not be confined to our little solar system, large as that seems, but would doubtless follow the same sequence of events in those centres of energy which are visible to us as stars; probably also in those which, though invisible, there is reason to believe exist in numbers through the immensity of space. Photography has already disclosed the existence of stars which the eye cannot discover through powerful telescopes, and we can only conjecture that in those centres of energy similar cycles of change are progressing as in our own solar system. We can by means of the spectroscope form some idea of the composition of the sun and of the fixed stars, and we may take it for granted that so far as the spectroscope can disclose the constitution of bodies so far away, it is certain that some of the "elements" which we recognise in the sun are also present in the stars, in nebulæ, and in comets; but their discovery scarcely lends so much weight to the hypothesis of the compound nature of the elements as the remarkable results which Mr. Crookes has been able to show by operating on terrestrial elements in high vacua.

Turning to another branch of the subject, the origin of living matter, we find in the Rev. Dr. Dallinger an experimentalist and a patient investigator, who has no superior in the division of biology which relates to the origin and development of the minute forms of the animal and vegetable life. In his address as President (for the fourth year) of the Royal Microscopical Society, Dr. Dallinger gave an account of his *magnum opus*, which he modestly described as a "fragment"—a research which has required something like ten years of unremitting and careful observation. All the world is aware of the work done by Dr. Dallinger in the study of microscopic organisms, and most of those who are familiar with Darwin's views know that he long ago expressed the opinion that if we would learn how animals accommodate themselves to changed environments, and so produce what we call new species, we must study the minuter forms of life with unremitting attention. It is obvious that temperature must be a potent factor in the life-history of any organism, and especially, perhaps, in those which are little more than a cell containing protoplasm. Already familiar with the life-history of the monads, Dr. Dallinger determined to watch their behaviour under gradual increments of temperature, and although a new generation comes into existence every four minutes or so, it took years of observation to raise the temperature to the rather high point of 158° Fahr. The apparatus employed was kept in a room at a fixed temperature, and the water in which the organisms existed was in constant communication with the microscope stage, so that the minute forms of life could be observed at any minute, and the temperature of the surroundings could be raised by degrees or by half degrees, the thermostats now working controlling the variation to one-sixth of a degree Fahr. in twenty-four hours. Commencing at the normal temperature of 60°, four months were occupied in raising it to 70°, without, however, affecting the monads, which still went on with their multiplication by fission as vigorously as before. When a temperature of 73° was reached, however, an adverse influence seemed to be exerted on the organisms as regards their vitality and productiveness; but by keeping the temperature constant for two months the new generations became acclimatised, so to speak, and in another five months the temperature was gradually raised to 78°. Here, again, a long pause became necessary, while the process of adaptation went on, and during the interval a marked development of vacuoles was observed, on the disappearance of which it was possible to again raise the temperature. Long pauses, vacuolation, slow advance, were the three stages well marked in the life-history of the monads and these experiments, until the high temperature (for monads) was reached of 158° Fahr., at which point the experiment was unfortunately terminated by an accident. As the object was to carry the experiments on to a point at which the organisms would fail to respond to the change in their surroundings, the accident terminated the research; but it is, perhaps, scarcely necessary to mention that Dr. Dallinger has started another, which has been in progress for about a year with satisfactory results. Although the premature ending of the investigation was unfortunate, the work done remains, and the patient searcher after truth is enabled to tell the scientific world that by a gradual changing of the temperature he found that organisms which flourished at 65°, and were killed at 140°, were in the course of half a million generations capable of flourishing at a temperature of 158°, and were killed by a return to the original temperature of 60°. Here, then, we have proof that organisms can adapt themselves to changing conditions of a rather "trying" character, and another evidence lending support to the Darwinian theory. The great law of the origin of species is accepted by nearly all biologists nowadays almost as a demonstrated fact; in truth, the wonder is that it was not earlier seen that adaptation to changes of environment is the keynote to the grand music of Nature. It may be urged that the experiments having been made on organisms so minute as monads, there is no proof that similar changes could occur with higher animals and plants. There is no proof, it is true, but the inference is strong. We cannot observe the effects of a change of environment on half a million generations of the higher forms of life; but as they are all merely vast aggregations of cells, comparable in many respects to the monads, what reason is there to suppose that, given the time and the requisite conditions, we should not see as

much adaptation to circumstances in the higher forms of life as in these lowly monads? Nearly every fact that patient research drags to light makes for evolution, and those that appear to be in contradiction are probably only apparently so, needing but the touch of the master hand to make them fit in with the grandest theory ever formulated by the mind of man. The researches of Mr. Crookes and those of Mr. Dallinger have been known more or less fully to the scientific world for some time; but their results have been made public within a few days of each other, and by their combined effect cannot fail to induce scientific workers to dive still more deeply into the mysteries of Nature, and if possible to drag more of her secrets to the light. There is a limit beyond which we cannot go; but these researches, the results of which we have briefly described, lie at the commencement of the last stage, and point the way for future travellers.

FITZGERALD'S IMPROVED BATTERY PLATES.

AMONGST recent improvements in battery plates, mainly for use in secondary batteries, those recently patented by Mr. D. G. Fitzgerald, of 6, Akerman-road, Brixton, are noticeable for their general utility in voltaic cells. The invention at present referred to consists in the manufacture of plates, slabs, and masses, mainly composed of peroxide of lead in a dense and coherent form and suitable for use as negative elements in voltaic batteries without contact with any oxidisable material. In the negative element of lead secondary batteries of the ordinary form, wherein contact with the oxidisable metal—lead—obtains, the two substances mutually destroy each other, the peroxide oxidising the lead support and the latter converting the valuable peroxide into the inert monoxide. The elements to be described have the great advantage of being free from this cause of deterioration. It has before been proposed to employ glycerine in admixture with oxide of lead for the manufacture of negative elements for voltaic batteries, but the patentee has experimentally found that a mixture of glycerine with about twice its volume either of water, or of a half-saturated solution of sulphate of ammonia, or of one of the other solutions specified in his Letters Patent (No. 4671 of 1885), or, again, of a solution of an acid forming an insoluble or nearly insoluble salt of lead (such as sulphuric or phosphoric acid), gives better results than glycerine alone in admixture with oxide of lead. The advantage is to be attributed to the fact that with the aqueous mixtures the resulting compound of lead is hydrated, whereas when glycerine alone is used the resulting compound is necessarily anhydrous. In carrying out his invention the patentee mixes oxide of lead with glycerine and water, or with glycerine and the solution of a suitable salt, or with glycerine in admixture with a suitable acid, and forms plates, slabs, or masses of one of these compositions, which speedily harden and may be afterwards converted into peroxide by "browning" by means of hypochlorite of magnesium or other suitable chlorine compound, and completing the conversion by electrolysis. The invention also relates to the production of a compound peroxide of lead element consisting of a central core or support of either of the glycerine and oxide of lead compounds above referred to, with an external layer or layers of one of the more porous and more readily convertible oxide of lead compositions. The method of construction adopted is as follows:—First, there is formed in a suitable mould a plate, *a*, with apertures or perforations (as shown in face view in Fig. 1), composed of oxide of lead made into a paste with any of the glycerine mixtures above referred to. Secondly, when this plate has hardened sufficiently the plate is converted, at least superficially, into peroxide of lead. Thirdly, the patentee attaches to the peroxidised plate, by means of ebonite screws passing through the apertures *b b* and b^1 b^1 and secured by ebonite nuts, the contact piece, of which an inside face-view is shown in Fig. 2. This consists of a thin strip of ebonite *c* (or other suitable material not acted upon by dilute sulphuric acid and not readily oxidised), to which may be attached, by cementing or otherwise, a piece of metal, *d* (which may be copper protected from corrosion by an insulating material), to which strips, *e e*, of platinum are metallically connected, the strips extending along inner face of the ebonite strip so as to be thereby pressed into direct contact with the peroxidised plate. The strips lie across notches, *f*, in the ebonite strip, so as to expose a portion of the outer surface of the platinum strips for contact with the external layer, *g*, of lead composition. Fourthly, the patentee coats to any required thickness one or both of the sides of the superficially peroxidised plate with a layer, *g*, of any of the porous and readily peroxidised oxide of lead compositions. This composition, which also covers the contact piece, is pressed through the holes or notches *f* to make contact with the platinum strips, as shown on an enlarged scale in Fig. 3, which is a cross section of part of the compound structure.

FIG. 1.

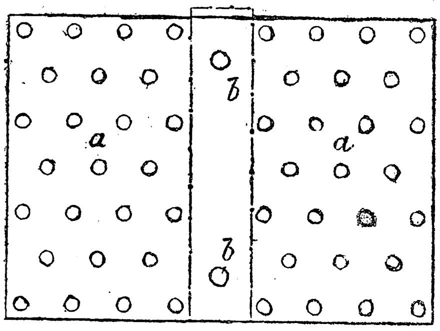

FIG. 2

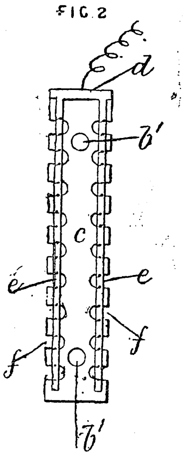

FIG. 3

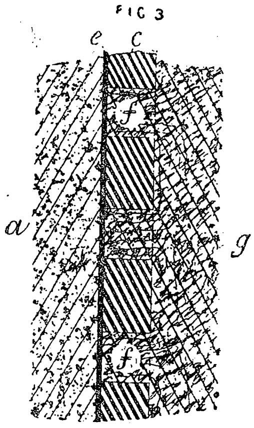

It may be applied either in the form of a paste or as a powder which, after being subjected to a slight compression, is moistened by suitable means—as by water spray, water condensed from steam, or by imbibition through porous plates by which the mixture may be confined. Lastly, the porous composition is converted into peroxide of lead by being made the anode in a suitable electrolyte, as is well understood. By making contact directly with the superficially peroxidised core as above described, a conductive surface of large area is obtained, from which the subsequent conversion of the external layer may be rapidly initiated. In practice it is found advantageous to prepare or coat that portion of the surface of a peroxide of lead element where contact is to be established with plumbago, or blacklead, the minute quantity of plumbago thus employed filling the pores in the plate and rendering it easy to establish a more perfect contact with the plate than would otherwise be possible, whether such contact be effected by platinum strips as above described or by means of a contact piece made of carbon.

LAKE TAHOE, long regarded as the deepest fresh-water lake in the United States, must now take the second place. Captain C. E. Dutton, of the U.S. Geological Survey, made, in July, 1886, a series of soundings at Crater Lake, Oregon, with unexpected results. The mountain wall that surrounds the lake is 900ft. high, the average depth is 1,500ft., and the maximum 1,996ft.

The method of finding the Sidereal Time at Local Mean Noon at any other Station will be found on p. 382.

On rare occasions a spot, or spots, may reward the sedulous observer of the Sun.

At 10 p.m. on the 20th the Sun, as it is said, "enters Aries," and this is the supposed time at which Spring commences. He is really at that point in the Constellation Pisces, where the Equator, the Ecliptic, and the Equinoctial Colure intersect. This, too, is the theoretical date of the Equinox; but the nearest approach to the equality of day and night will occur in London on the 19th, when the Sun will be 12 hours above the horizon, and, of course, 12 hours below it. The Zodiacal Light may now be seen in the West after sunset on every clear, moonless evening.

The Moon

Enters her First Quarter at 1h. 7·8m. in the early morning of the 3rd, and is Full at 8h. 33·9m. p.m. on the 9th. She will enter her Last Quarter at 1h. 42·1m. p.m. on the 16th, and be New at 4h. 9·7m. in the afternoon of the 24th. High tides may be looked for on and about the 9th.

Day of Month.	Moon's Age at Noon.	Souths.
	Days.	h. m.

31	6·8	5 26·2 ,,

The Moon will be in conjunction with Saturn at 2 p.m. on the 5th; with Jupiter at 8 p.m. on the 12th; with Mercury at 3 a.m. on the 24th; with Mars at 5 a.m. on the 25th; and with Venus at midnight on the 26th.

Mercury

Is an Evening Star, in the sense of Southing after noon up to the 21st. He attains his greatest elongation East of the Sun (18° 9′) at 11 a.m. on the 5th, and, travelling then pretty rapidly to the Westward, comes into inferior conjunction with the Sun at 3 a.m. on the 22nd. During the first week or ten days in March, Mercury may be caught by the naked eye glittering over the Western point of the horizon just after sunset. His diameter increases from 6·4″ at the beginning of the month to 11·2″ by the 22nd, diminishing to 10·6″ by the 31st.

An illustrated explanation of this table will be found on p. 384.

cated in the above ephemeris lies in a region in Pisces destitute of any conspicuous stars whatever.

Venus

Is an Evening Star throughout the month; but presenting merely a gibbous disc increasing almost imperceptibly from 10·8″ on the 1st to 11·6″ by the 31st, she is comparatively destitute of interest as a telescopic object. Like Mercury, she may be caught glittering over the Western horizon after sunset.

Day of Month.	Right Ascension.	Declination.	Souths.
	h. m.	° ′	h. m.
1	0 8·0	0 20·2 S.	1 31·9 p.m.
6	0 30·5	2 15·7 N.	1 34·7 „
11	0 53·0	4 50·5 „	1 37·4 „
16	1 15·6	7 22·8 „	1 40·3 „
21	1 38·4	9 50·9 „	1 43·3 „
26	2 1·4	12 13·5 „	1 46·6 „
31	2 24·7	14 28·8 „	1 50·2 „

Hence it will be seen that, starting from a point at no great distance from the (so-called) "First Point of Aries," Venus will traverse the Eastern half of the Constellation Pisces, and terminate her path in Aries.

Mars

Is still invisible.

Jupiter

Viewed in relation to his Southing, is a Morning Star; but he rises soon after 10h. 30m. on the night of the 1st, and at about half-past eight o'clock in the evening of the 31st. He is, however, but indifferently situated for the observer. His equatorial diameter increases from 38·2″ on the 1st to 40·8″ by the last day of the month.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	14 15·6	12 6·7	3 41·1 a.m.
6	14 14·9	12 2·1	3 20·7 „
11	14 14·0	11 56·1	3 0·1 „
16	14 12·7	11 48·7	2 39·2 „
21	14 11·2	11 40·1	2 18·0 „
26	14 9·4	11 30·2	1 56·6 „
31	14 7·5	11 19·4	1 35·0 „

The short retrograde arc shown above lies a little to the North of the 5—4 magnitude star λ Virginis.

Saturn

Is visible during the whole of the ordinary working hours of the night, but should be looked at soon after dark to be seen to the greatest advantage. His great height above the horizon at this time places him in a peculiarly favourable position for the observer. As we have recently remarked, it will be noted that the South Pole of the planet entirely covers Cassini's division, and is, in fact, practically coincident with the outside edge of ring A. His equatorial diameter decreases insensibly from 17·6″ to 16·8″ between the beginning and the end of the month.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	7 8·5	22 26·1	8 31·2 p.m.
6	7 8·0	22 27·5	8 11·1 „
11	7 7·7	22 28·6	7 51·1 „
16	7 7·6	22 29·4	7 31·3 „
21	7 7·6	22 29·8	7 11·7 „
26	7 7·9	22 29·9	6 52·3 „
31	7 8·4	22 29·6	6 33·1 „

This almost imperceptible pendulum-like arc is described a little to the West, and just to the North, of δ Geminorum.

Uranus

Is now visible during the major part of the working night, as he rises between 8 and 9 p.m. at the beginning of March, and between 6 and 7 o'clock in the evening at the end of it. He comes into Opposition to the Sun at Noon on the 31st. Of course, having South declination, the nearer he is to the meridian at the

time of observation the better. His angular diameter is 4″ throughout the month.

Day of Month.	Right Ascension.	Declination South.	Souths.
	h. m.	° ′	h. m.
1	12 44·1	3 57·3	2 5·8 a.m.
6	12 43·4	3 53·1	1 45·4 „
11	12 42·7	3 48·6	1 25·0 „
16	12 42·0	3 43·8	1 4·6 „
21	12 41·1	3 37·9	12 44·3 p.m.
26	12 40·3	3 32·9	12 23·8 „
31	12 39·5	3 27·9	12 3·3 „

Whence it will be seen that Uranus describes a short retrograde arc to the South-east of γ Virginis.

Neptune,

To be seen at all, must be looked for the moment it is dusk, as he rises and Souths in bright sunlight. As, however, he does not set until after midnight, we give an ephemeris of him for the first fortnight in March, after which it would be simply a waste of space to continue it.

Day of Month.	Right Ascension.	Declination North.	Souths.
	h. m.	° ′	h. m.
1	3 33·2	17 26·0	4 56·5 p.m.
6	3 33·5	17 27·4	4 37·1 „
11	3 33·8	17 29·0	4 17·9 „

Hence Neptune is still to be found in that blank region of the sky a little more than 6° to the South and West of the Pleiades.

Shooting Stars

May be looked for between the 1st and the 4th, and again on the 16th.

Greenwich Mean Time of Southing of Eleven of the Principal Fixed Stars on the Night of March 1st, 1887.

Star.	Souths. h. m. s.
α Leporis	6 50 43·69 p.m.
α Orionis	7 11 58·70 „
Sirius	8 2 57·52 „
Castor	8 50 3·32 „
Procyon	8 56 2·06 „
Pollux	9 1 2·16 „
β Cancri	9 32 56·21 „
α Hydræ	10 44 23·57 „
Regulus	11 24 36·05 „
α Ursæ Majoris	12 18 51·42 „
δ Crateris	12 35 44·89 „

The Method of finding the Greenwich Mean Time of Southing of either of the Stars in the above List for any other night in March, as also that of determining the Local instant of its Transit at any other Station, will be found on p. 384.

PAPIER-MACHE.

THE manufacture of papier-mâché (literally, "chewed paper") forms an important branch of the paper industry. Who does not remember those projectiles of our school days which we called "spit-balls," and which when thrown at a wall or ceiling adhered thereto with tenacity? What was most striking about these balls was their extraordinary hardness after they became thoroughly dry, this being the more marked in proportion as the chewing had been more perfect. It was through observing such hardness that the idea occurred to some one to employ paper pulp in the manufacture of various objects. Yet the substance employed in the industry is not a "mashed" paper in the absolute sense of the word, but is a paper converted into a soft cardboard by mechanical processes. In the manufacture of papier-mâché, the raw material used is a bluish-grey, unsized, strong, fine-grained paper. The sheets may be compared (whiteness, which is of no account, being excepted) to Annonay lithographic paper. Cotton forms the basis of it. These sheets are pasted together by means of a layer of dextrine or starch, applied with a steel spatula. When the desired thickness has been obtained, the mass is put into a hydraulic press that operates in a highly heated drying room. Under the immense pressure of this apparatus there forms a solid block, which is as hard as boxwood or ebony, and which is perfectly plane or has the form of the mould in which the raw material, so ductile when moist and so hard when dry, was compressed. It can be moulded into any shape whatever, that of table legs, chair arms, rose-work, mouldings, &c. This sort of wood, without pores, sap, fibres, and knots, is capable of being worked with the saw, the gouge, the rasp, and the lathe. It can be polished, if need be, although this operation is reserved for the thick black varnish that is applied to it in several coats, with an intervening stay of a night in a very hot air-heated drying room. When it comes from the latter the varnish is very hard, and is free from blisters and cracks. It is possible that many of the objects that are offered to us as being finished with Japan or Chinese lacquer are merely impregnated and covered with a mixture of gum copal, bitumen, tar, resin, and other hydrocarbons impregnated with lampblack and colour in certain proportions. The baking is the important point. When this operation has been too greatly prolonged, the varnish scales off and cracks; and when it has not been carried to a sufficient extent, the surface remains sticky. It is not necessary, then, to exceed a certain temperature, always higher than 100°. This moulded and pressed paper can be easily turned in the lathe, and made into light indestructible balls and beads, or be fashioned into inkstands, caskets, and cylinders. It is from this substance that are manufactured all those bracelets of large black beads studded with imitation diamonds, all those necklaces, pins, clasps, and trinkets of all sorts that are taken for jet or some precious wood. Again those handsome bracelets composed of semi-lucid and opaline globules that seemed to have been cut out of a stone formed of concentric layers, like certain precious stones, are merely of papier-mâché, cemented with white varnish and coated with the same. So, too, those beautiful nacreous, painted, and gilded trays, round tables, and caskets that are known as Japanese work are merely papier-mâché. The Japanese know but one kind of gilding, while we have two—the dead and the brilliant. We have, likewise, a liquid nacre taken from the scales of the aiblette (bleak) that well imitates the white currant and certain transparent berries. The nacre is solidly inlaid by means of the hydraulic press, and finally the surface is finished with pumice-stone in order to make it perfectly even, and covered with a colourless varnish of the first quality.—*Bull. des Fabricants de Papier.*

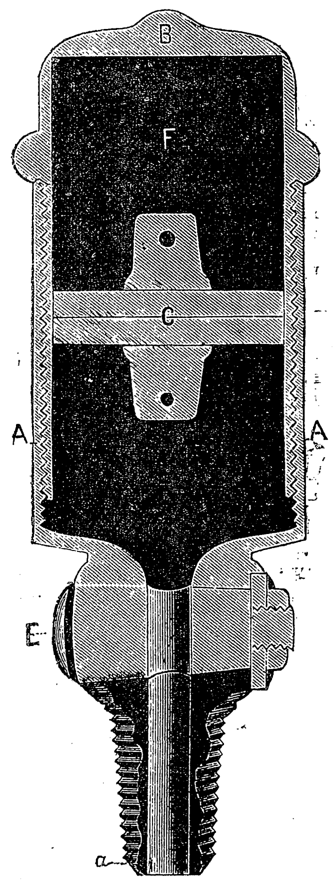
THE POTATO AT REST.

WE are so accustomed, at this season, to think of the potato as an inert object when at rest, that we are apt to overlook the fact that the rest is only partial, whilst underneath that impassive and immobile looking skin a good deal of work is going on—at least, whenever the temperature is above freezing. Some knowledge of the nature of that work is desirable for us as practical men, because upon the way in which it is done depends, in great measure, our success in storing potatoes for consumption, and the vigour and health of our crops for the future. Much of the complaint made of late as to the degeneracy of the potato, and as to its inferior quality as compared with past times, is probably due to the way in which these changes are effected. These again are dependent upon the way in which the plant was able to do its work in the preceding summer. This brings us to the questions whether the newer varieties are as well adapted to our climate as the older ones, and whether the exhibition table has not something to answer for by fostering good looks at the expense of constitution; at any rate, these matters are worth consideration. If an ordinary grower of, or dealer in, potatoes were told that the tubers he rightly sets such store by breathe as human beings do, he would probably think that some facetious hoax was being played upon him. The fact, however, remains that, although they have no lungs, potatoes, in the ground or out of the ground, breathe. We do not mean to say that they palpitate, draw long breaths, or heave deep sighs, but they breathe nevertheless. They inhale and exhale through their skin gases of various kinds, just as every one knows that under certain conditions they exhale moisture or "sweat." The conversion of the sugary juice called glucose, derived from the foliage, into the solid starch stored up in the tuber, is associated with the emission of gases, while the reconversion of that starch into soluble sugar requisite for the maintenance and nourishing of the tissues of the tuber, and for the shoots when growth commences, is also attended by an emission of carbonic acid gas and watery vapour, this latter process being more or less analogous to that which constitutes the respiration of animals; and thus it is that potatoes breathe. Starch grains are practically insoluble, and are too large to be conveyed in their solid form from the leaves in which they are formed to the tubers in which they are to be stored up; hence the necessity for their conversion into glucose, or some analogous liquid matter by means of which the transit may be made, and from which the solid starch may be again deposited as occasion may require; so that potato tubers, whether still in the ground, or removed and placed on the exhibition-table, or in the cellar, are, in a certain way, breathing.

The chemical changes we have alluded to go on probably through the agency of some ferment in the detached tuber in the same manner, but to a less extent, than when it is still attached to the plant. A kilogramme (2lb. 2oz.) of potatoes when the temperature was 20° C. (68° F.) gave off in August 6·5 milligrammes of carbonic acid per hour, and in January and February, at the same temperature, 10 and 11 milligrammes per hour. When exposed, however, to the freezing point in the laboratory, whether in August or in the winter months, the proportion of carbon dioxide, *alias* carbonic acid gas, was reduced to about two milligrammes per hour. As the temperature rises, more and more sugary juice is found in the tubers, less and less starch. A time comes when the sugar is no longer used up in the course of the respiratory process, and no longer converted into starch. An excess of sugary juice then occurs, which flows to the eyes or buds, and the period of comparative rest is at an end. The practical inference is that which careful practitioners have long arrived at from experience—viz., to store the potatoes in a uniform low temperature, in a dry condition, and in the dark, so as not to excite those chemical and physical changes associated with growth, and consequent upon the conversion of starch into sugar. Mr. H. Müller, who has investigated these matters, has extended his researches to the buds of trees, in which exactly the same phenomena take place as in the tubers of the potato. When the flow of sugary juice from the leaf ceases at the end of autumn, and is deposited in the form of starch in the buds, bark, and young wood of the tree, growth ceases. In the spring a little of the sugary juice left over in the bark flows towards the buds, which forthwith begin to swell and lengthen into shoots.—*Gardeners' Chronicle.*

COMPRESSED-AIR GREASE CUP.

THE great merits of the grease cup shown in the accompanying sectional view are its simplicity of construction and its automatic and



continuous feed. It is designed for the manipulation of grease or "dope," a composition which, for some purposes, is superior to oils. The cup feeds the grease continuously till emptied, and requires no attention whatever beyond the mere filling from time to time. The cup A A is provided with a regulating valve, E, above the outlet orifice *a*. B is a hollow cap, provided with an air-tight piston, C, with hydraulic packing. The operation is as follows: The cap being removed, the piston is drawn in to supply air to the air chamber F. The packing of the piston and the inside of the cap are

slightly greased, to reduce the friction to a minimum. The piston is then replaced in the mouth of the cap, when the cup is filled completely with grease. The cap is then screwed down the entire length of the threads. As the piston C, located within the cap, is forced inward, it is evident that a quantity of air will be confined and compressed in its rear, in the chamber F. It will be seen, therefore, that upon the opening of the regulating valve E sufficiently to permit the proper amount of grease to escape, the compressed air in the rear of the piston is allowed to expand, exerting a constant and even pressure upon the grease to force it from the cup, this action being automatic. As the attendant has absolute control of the outflow of the contents, by means of the valve, the economy and convenience of the cup are assured. This cup, according to its size, will manipulate its contents in from six days to two months. No matter in what position the cup may be placed, the grease is always forced to the bearing, making it most valuable for loose pulleys. Any further information may be obtained Mr. John C. Grout, 17 Newberry and McMillan Building, Detroit, Mich., who is the sole manufacturer of these cups.—*Scientific American.*

SCIENTIFIC SOCIETIES.

ROYAL METEOROLOGICAL SOCIETY.

THE usual monthly meeting of this society was held on Wednesday evening, the 16th inst., at the Institution of Civil Engineers, 25, Great George-street; Mr. W. Ellis, F.R.A.S., President, in the chair. Mr. E. T. Edwards, Mr. D. Fitzgerald, C.E., Mr. T. B. Groves, F.C.S., and Mr. W. W. Midgley were elected fellows of the Society.

The adjourned discussion on the Hon. R. Abercromby's paper on "The Identity of Cloud Forms all over the World, and on the General Principles by which their Indications must be Read," was resumed, and the following papers were read:—(1) "Remarks Concerning the Nomenclature of Clouds for Ordinary Use," by Prof. H. H. Hildebrandsson, Hon.Mem.R.Met.Soc. (2) "Suggestions for an International Nomenclature of Clouds," by the Hon. R. Abercromby, F.R.Met.Soc. Both Prof. Hildebrandsson and Mr. Abercromby have paid great attention to the question of the forms of clouds, and having recently conferred together, they have agreed to recommend for international use the following ten principal varieties—viz., High-level Clouds: Cirrus, Cirro-stratus, Cirro-cumulus; Middle-level: Strato-cirrus, Cumulo-cirrus; and Low-level: Cumulus, Stratus, Strato-cumulus, Nimbus, Cumulo-nimbus. (3) "The Influence of Weather on the Proportion of Carbonic Acid in the Air of Plains and Mountains," by Dr. W. Marcet, F.R.S., and M. A. Landriset. The authors give an account of some experiments which they have made in the proportion of carbonic acid in the air at Geneva and on the summit of the Dole, the highest point of the Jura chain, the difference in altitude being 4,193ft. The results of these experiments show (1) that in fine, clear weather on a mountain chain of moderate Alpine altitude and in the adjoining valley or plain the atmosphere holds the same mean proportion of carbonic acid at both places; and (2) that when the summit of a mountain chain is in a fog, a circumstance which frequently happens in an Alpine district, the air in the fog contains a smaller proportion of carbonic acid than it would hold in fine, clear weather.

The Secretary, Dr. Tripe, read a letter received from Sir F. Abel, Organising Secretary to the proposed Imperial Institute, inviting the Society to draw the attention of the Fellows to the undertaking, with the view of their contributing towards it.

The President stated that copies of the letter and of the accompanying paper, explanatory of the scheme, would be forwarded to each Fellow.

LIVERPOOL ASTRONOMICAL SOCIETY.

THE usual monthly meeting was held on Monday, 14th February. The chair was occupied by Mr. W. D. H. Deane, M.A. Seventeen members were elected, and 23 candidates proposed, and His Imperial Majesty the Emperor of Brazil was elected an Associate of the Society.

The Secretary said he had an important matter to put before the meeting. The Pernambuco branch had now become so extended as almost to form a society in itself. At present, owing to the uncertainty and delay of postal communication, it was quite possible for a candidate not to receive official notice of his election until nearly five months from the date of his nomination, and, of course, the difficulty was felt in other ways. Under these circumstances they had asked for the power of electing their own members and a president and local executive, so that they might be enabled to hold meetings and pass such by-laws as might be found necessary for their welfare. It was understood that all decisions were to be subject to the confirmation of the home council. Strictly speaking, this was a matter which rested with the council only; but, though they were not unwilling to grant the concession, the question was of so much importance that they preferred its being discussed at a general meeting.

The President, in a letter, had expressed his pleasure at finding that the South American members deemed themselves strong enough to form a local branch. Although perhaps some might say that such a course was inexpedient, yet, for his part, it seemed that as the objects they had in view were the growth of their science, nothing could be more in keeping with the Society's aim than the formation of local and quasi-independent branches. Whilst preserving its attachment to the old society, the new branch would itself be a centre from which in due course other branches might be put forth in South America. The constitution of such a branch as was contemplated would need care, and should be so formed as to consolidate their relations, and, at the same time, to leave perfect freedom to each other. He, Mr. Espin, would suggest that the head of the new branch be not called "President"—because the head of a society like the L. A. S. is, *ipso facto*, president of all its branches—but *vice* president, and, as such, being head of the especial branch, and at the same time having an office in the home society next to the president himself.

Mr. James Gill was strongly in favour of granting home-rule to all the branches. Without some form of local government it would be impossible for distant members to hold meetings, and so to encourage each other in a study of the science. As long as their regulations were subject to the control of the home council he did not see that there could be any objection.

Mr. C. A. Defieux said the isolated position of the South American members gave them every claim to their sympathy. He thought it might well be left to the discretion of the members what title they gave their officers, since it would only have a local significance, and would not affect their status in the home society.

Mr. J. L. Coxon asked whether the course that had been proposed would affect the amount of their subscriptions, as he understood that this was already too small to cover the expenditure.

Mr. Davies replied that the difference would, if anything, be in their favour. Foreign correspondence was rather a costly luxury, and there would also be some saving in the carriage of parcels. The local expenses would of course be borne by the members themselves, but it was only fair that each branch should be supplied with stationery, and other necessary items. It was not, however, entirely a question of economy. The Society had now become so widespread that some such division was absolutely necessary if the work was to be carried on. He did not think the responsibility of the Society ended with supplying publications, which, however valuable they might be in other respects, were not always suited to the requirements of beginners. Astronomy appeared to be rather backward in South America, and there was, besides, a scarcity of astronomical works. To make up for this there was plenty of enthusiasm, and monthly circulars were issued by the more advanced members, containing a glossary of astronomical terms, and such other information as they thought might be useful. A taste for their science had evidently been awakened, and it lay with the members of the home society to say whether it should be encouraged.

The Chairman said if there were no other remarks he would put it to the meeting in the form of a resolution, which, being done, was unanimously adopted.

Mr. W. H. St. Q. Gage submitted a list of coloured stars which he had observed during his late residence in India. The observations had been made with a $4\frac{1}{4}$ refractor at an altitude of 6,000ft.

A paper was read on the proper motion of 40 (o^2) Eridani, by Mr. J. E. Gore. In addition to the binary companion to this interesting ternary system, two other faint *comites* had been measured, and from these measures he had computed the proper motion of the principal star. This afforded a mean result of 4·07″ annually in the direction of position angle 212·4°.

Miss E. Brown called attention to a possible transit of Vulcan across the semi-disc during its approaching node, which, according to Oppolzer, was due on the 18th March.

Papers were also read on the variability of LL. 14551 (U Puppis), by Mr. Herbert Sadler; on the Merope nebula, by Mr. W. H. Wesley; on the lunar formation Straight Wall, or "Railroad," by Mr. T. G. Elger; on some typical sunspots, by Major E. E. Markwick; on a suspected variable in Ursa Major, by Mr. S. M. Baird Gemmill; on secular change of climate, by Mr. M. Fergus, and Mr. W. F. Denning continued his series of papers on telescopes and telescopic work.

SCIENTIFIC NEWS.

ANOTHER faint comet has been discovered by Mr. E. E. Barnard, of Nashville, Tennessee. On Feb. 15, at midnight, local time, its position was R.A. 8h. 4m. 8s., S. Dec. 16° 10′; moving rapidly north-west. It will be comet D 1887. Nashville is in lat. 36° 8′ 58·2″ N.; long. 5h. 47m. 12·77s. W.

From Dun Echt Circular No. 136 we learn that Dr. H. Oppenheim, of Berlin, has calculated elements and ephemeris of Barnard's comet (C 1887) from observations made at Cambridge, Mass., Paris, Vienna, Padua, and Scarborough: T = 1886 Nov. 26·46785, Berlin M.T.; $\pi - ☊$ 30° 1′ 49·2″; ☊ 257° 48′ 17·4″; i 85° 30′ 25·2″; log. q 0·16398. The position at Berlin midnight is given as—

	R.A.	N. Dec.
Feb. 26	20h. 51m. 20s.	45° 44·1′
28	20 58 34	46 50·6

Prof. Jules Béclard, the well-known Dean of the Faculty of Medicine, and perpetual secretary of the Paris Academy of Medicine, died rather suddenly recently of pneumonia, at the age of 69 years. His principal work is the "Traité de Physiologie Humaine," which is in its seventh edition, and is the standard textbook for French students.

Dr. Pebal, Professor of Chemistry at the University of Graz, was assassinated last week by a discharged servant, who afterwards committed suicide.

At a recent meeting of the Linnean Society Brigade-Surgeon J. E. T. Aitchison read a paper on the "Fauna and Flora of the Afghan Boundary," the zoological specimens obtained comprising about 20 species of mammals, 130 species of birds, 35 species of reptiles, 7 species of fish, and over 100 species of insects—many new to science. The botanical specimens amount to 800 species, over 100 being new to science.

The Statistical Society has received a royal charter, dated January 31, by which it is incorporated under the style of "The Royal Statistical Society."

The Society of Science Bronze Medal for Inventions has been awarded to Mr. E. R. Dale, of Christchurch.

At the Royal Institution on Saturday (to-morrow), Lord Rayleigh commences a course of six lectures on "Sound."

Mr. H. C. Russell, Government astronomer, New South Wales, will represent that colony at the Conference of Astronomers to be held in Paris next April.

The Cunard liner *Etruria* has eclipsed her own best performance, for leaving the bar of the Mersey on Saturday, Feb. 12, at 4 p.m., she arrived at New York bar at 6 a.m. on the following Saturday—a passage of 6 days 19 hours. The route taken was, as usual with the Cunarders, the most southerly and longest, to avoid icebergs, and the performance must represent a mean speed of 19 miles an hour. Some of the vessels of the Cunard line are being fitted with gun platforms on the turtle decks, fore and aft, so that they can be at once converted into armed cruisers should an emergency arise.

The official trials of some torpedo-boats built for the Turkish Government by Mr. de Vignes and Messrs. Maudslay, were made recently in Long Reach, when mean speeds of 21·7 knots were obtained, the highest speed being 23·4 knots, or nearly 27 miles an hour. The vessels are 126ft. long, with 15ft. beam, and have three cylinder compound engines.

According to an American paper, the revolution impending in the construction of locomotives—the use of four cylinders instead of two, one pair for each driving-wheel axle—is due to the success of the triple expansion engines on ocean steamers. Not that compound engines are to be used for locomotives; but because a number of cylinders aggregating the same power will save coal. The fact that the present system is not the best has been well known for a long time. The transmission of power through the connecting-rods to the two drivers is an uneconomical way at best. We presume the "revolution" refers to American practice.

The Bill empowering the North Metropolitan Tramway Company to employ electricity on

their lines has passed the House of Lords, and it is expected that in a short time Mr. Elieson's electric locomotives will be in regular work on the Romford-road between Stratford and Manor Park.

The Sprague Electric Railway and Motor Company are running thirteen elevators in Boston, Mass., both freight and passenger. One of the freight elevators is the largest in the city. They also have fifty other motors in operation.

In making comparisons between gas and the electric light in New York it is not unusual to refer to the high price of gas in that city. It should be remembered that the illuminating power is rarely less than 20 candles, while about half the companies supply gas of 25 to 30 candle-power.

The Gasmotoren Fabrik, of Deutz, near Cologne, have recently constructed a two-cylinder Otto engine which gave about 60 horse-power on the brake when driven by Dowson fuel or water-gas. They have in course of construction a four-cylinder Otto engine, which is to develop over 100 horse-power and have an impulse at every stroke.

A correspondent of one of the daily papers has been making a comparison of the sunshine records as taken at Kew and St. Leonard's, and gives his results for the present month. For the week ending 2nd February—Kew, 7 hours; St. Leonards, 21·2 hours; 9th February—Kew, 12 hours; St. Leonards, 25·6 hours; 16th February—Kew, 13·5 hours; St. Leonards, 30·2 hours. Total—Kew, 32·5 hours, against 77·0 hours at St. Leonards, or in proportion of 5 to 12.

From observations made by Herr Schiller, a German architect, it appears that the radius of the circle protected by a lightning-rod is not more than twice the height of the rod.

The German Chamber of Commerce having been asked recently by the German Fishery Association to assist in the destruction of seals by putting a premium on them, has refused. The seals consume enormous numbers of herrings; but we suspect that they are more valuable than the fish they eat.

The international jury appointed by the King of the Belgians to award his prize of 25,000f. (£1,000) for the best work on the means of popularising the study and developing the teaching of geography, has awarded it to Mémoire No. 7, by Prof. Anton Staubers, of the Royal Gymnasium, Augsburg. The president of the international jury was Lieut.-Gen. Liagre, formerly Belgian Minister of War, the Secretary of the Royal Belgian Academy of Sciences, the other members of the jury being Commandant le Bon, of the French Legation, Colonel de Tchitchagow, of the Russian Legation, Sir Travers Twiss, Q.C., member of the Royal Society of Geography of England; His Excellency Valera, Minister of Spain at Brussels; Prof. Van Beneden, of Louvain; and Major-Gen. Wouvermans, President of the Royal Society of Geography of Antwerp. It is to be hoped that this essay will be translated and published in a variety of languages.

The permission to grow tobacco for experimental purposes, under the usual regulations and guarantee to the Inland Revenue Department, has been extended to the present year.

At a recent meeting of the Berlin Geographical Society Herr Standinger, a member of the last Flegel expedition, gave an account of the journey from Benue to Kano, Sokoto, and Gandu. While waiting at Saria, an expedition was made to Kano—a six days' journey. Many villages lay on the road, which was so frequented that women found their living on it by offering food to sell. Shells are used as money. Kano is a well-fortified place, of imposing appearance. The king, who received the expedition with hospitality, is considered a mighty prince. His palace is a high dome-shaped edifice, the walls of which are decorated with brass basins. It is wonderfully built of mere clay; bricks are unknown. There is a flourishing trade with the North, carried on by means of dromedaries. On returning to Saria the expedition were much incommoded by curious visitors and sick people wanting medicine. There is a well-developed industry in leather and braided goods, the dyeing of which is a secret.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the EDITOR *of he* ENGLISH MECHANIC, *332, Strand, W.C.*

All Cheques and Post-office Orders to be made payable to J. PASSMORE EDWARDS.

*** *In order to facilitate reference, Correspondents, when speaking of any letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

"I would have everyone write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things knows no more than what everybody does, and yet, to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks, a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

JUPITER'S SATELLITES—SOME VERY UN-"NATURAL PHILOSOPHY"—THE AGE OF THE EARTH—WHAT CAUSES DAY AND NIGHT?—A PLUMB-LINE TRANSIT INSTRUMENT—THE IMPERIAL INSTITUTE—THE "JOURNAL" OF THE ROYAL MICROSCOPICAL SOCIETY—THE LIVERPOOL ASTRONOMICAL SOCIETY—REPORT OF THE HARVARD COLLEGE OBSERVATORY: AND OF THE "WARNER" ONE AT ROCHESTER, N.Y.—THE STELLAR WORK OF MR. EDWIN F. SAWYER—THE PRESIDENT'S ADDRESS AT THE ANNUAL MEETING OF THE ROYAL ASTRONOMICAL SOCIETY—PHOTOGRAPHS OF STARS AND ANONYMOUS WRITERS—THE ACHROMATISM OF LENSES—GREGORIAN TELESCOPE.

[26868.]—FELLOWS of the Royal Astronomical Society will doubtless recollect a valuable paper which appeared in Vol. XLV. of our *Memoirs* by Professor Souillart, of Lille, on the "Théorie Analytique des Mouvements des Satellites de Jupiter." In the year (1879) when this appeared the French Academy increased the value of the Damoiseau Prize to 10,000 francs, to be awarded for the best solution of the problem of the theory of the movement of the satellites in a more general and complete form, making it include the construction of fresh tables for each satellite. Pursuing his research, M. Souillart has arrived at results of a nature such that (albeit the numerical calculations are not quite complete) the committee regard his theoretical conclusions as of sufficient importance to entitle him to the prize; which they have, consequently, awarded to him. I shall look forward anxiously and curiously to the completion of the merely numerical work, inasmuch as, this once finished, we may reasonably hope that the director of our own *Nautical Almanac* will lose no time in availing himself of the results of this gifted and indefatigable Belgian savant.

As "Blair's Grammar of Natural and Experimental Philosophy" is a work with which I am unfamiliar, I cannot, of course, judge whether the whole of its statements are as trustworthy as that quoted by "T. C. H." in letter 26812 on p. 520. If so, though, he might spare his copy to his housemaid for the purpose of lighting the fire, without any appreciable loss whatever. The earth was in perihelion this year on January 2nd at 8 p.m., at which date (and for some days before and after it) the apparent diameter of the sun was 32′ 36·4″. At 9 a.m. on July 2nd the earth will be in aphelion, and for some days about that time his diameter will subtend an angle of 31′ 32·0″. So much for Mr. Blair's stuff about the sun's diameter. As to his extract from Sir Wm. Herschel, what that great observer really did see was, in all probability, two or three craters of sufficiently reflective power (like, for example, Aristarchus) illuminated by earth-shine on the moon's dark limb. Selenographers do *not* observe burning volcanoes on our satellite nowadays.

Would it be asking "E. L. G." (letter 26832, p. 524) too much if I were to beg him to favour us with some evidence that "this earth was ages older than the sun," and "that there are many worlds having time marked by days, evenings, and mornings, though without a sun as yet"? I only crave a little information on these two points to begin with. As for the fresh sea that fell from the sky 50 centuries ago! your able, if slightly eccentric, contributor has gone on repeating this until I am convinced he really believes it himself.

With reference to the query with which Mr. West concludes reply 61307 (p. 525), the smaller the hole and the farther the plumb-line is from it, the more likely he will be to attain accurate results. Were the wire only 4ft. from the eye-hole, a very small lateral movement of the eye would cause a sensible parallactic displacement of it.

I have received, in an official capacity, a circular from Sir F. Abel (couched in terms which may be summarised in "Your money or your reputation for loyalty"), requesting me to head a movement in my own neighbourhood for raising funds for the Imperial Institute, which is, I gather, to be erected at South Kensington. What this means it is needless to insist on here; but I should like to ask if my correspondent is the same Sir F. Abel who was so active with a Sir Somebody Bramwell in planting the central building of the City and Guilds of London Institute in the midst of the Brompton Ring—and if so, what are the chances of the innumerable berths in connection with the "Exhibitions" and "Technical Education" (which form part of the scheme of the Imperial Institute) falling into the hands of the members of that Ring? No information on this point is vouchsafed from Sir F. Abel's office; so I put the question here in the hope that some brother reader may be sufficiently behind the scenes to enlighten me. I certainly shall decline to part with my own money, or to appeal to anyone else for his, without some very specific assurance on this point.

I complained last year (letter 25273, Vol. XLII. p. 446) of the delay in the issue of the Title-page and Index of the Volume of the *Journal* of the Royal Microscopical Society for 1885. Such delay, I am sorry to say, seems apparently becoming chronic, as here we are getting towards the latter end of February, and the index for the volume for 1886 has never made its appearance. On the cover of Part I. (for February) for the current year there appears this notice: "The Index Number is delayed from exceptional and unavoidable causes; but will be issued shortly." Now, my modest protest in January twelvemonth elicited a letter (25329, Vol. XLII. p. 474) from "One Who Knows," who fell foul of me for omitting to inquire before I penned my remonstrance; so I thought that this year I would follow his advice, and *did* inquire accordingly: with the result that I was informed by the attendant that "he didn't know, but perhaps Mr. Crisp had been too busy to attend to it"! With the utmost deference to "One Who Knows," I can hardly regard the result of listening to his counsel as absolutely satisfactory.

I notice with sincere satisfaction in your "Scientific News" on page 540, that the Emperor of Brazil has been enrolled in the ranks of the Liverpool Astronomical Society. Nothing can possibly be more gratifying to all interested in the diffusion of sound knowledge of the chief of all the sciences than to note the rapid progress and brilliant success of this admirable association of amateur astronomers since its management has been taken from the hands of persons who were rapidly bringing it into a moribund condition, and reverted to those of its zealous, able, and indefatigable originators.

Some of my American friends have kindly forwarded me Reports of Observatories, &c., for 1886, which contain a great deal that is interesting to the astronomer, both amateur and professional. Among them the place of honour must be given to Professor Pickering's account of the work done at Harvard College Observatory during the year which has just closed. The photometric observations of the Eclipses of Jupiter's satellites have been continued, the total number of eclipses thus observed being now 358. It is quite needless to insist upon the very great value of these observations to the investigator of the Jovian system. Comparison stars for variables and the Novæ in Orion and Andromeda have been observed, star spectra photographed, places of comets obtained, and no less than 59,800 separate photometric comparisons made with the meridian photometer. In connection with this last branch of research, it may be interesting to note that a comparison of the 700 stars common to the observations of Wolff, Pritchard, and the Harvard Photometry showed an average difference between Harvard and Wolff (after allowing for systematic differences) of ·140 of a magnitude; and between Harvard and Pitchard, of ·145 of a magnitude, Wolff and Pritchard differing ·192 *inter se.* In the case of 55 stars, proposed by Professor Pritchard as standards, the average deviation from the Harvard Photometry was only ·104 of a magnitude. Comparisons have also been instituted between star magnitudes observed at Harvard with the meridian photometer, and at Pulkowa with a Zöllner's photometer, with the result that the average difference in brightness between stars observed at both places did not exceed ·1 of a magnitude. It is worth while to remark that Professor Pickering begins his report with a reference to a sum of 164,198dol., which has accrued to the Observatory under the will of Mr. R. T. Paine, raising the funds available for the support of work at the observatory to 398,046dol. A further fund of 13,380dol. has

also become available. Now, when one reads of so worthy an exercise of private munificence as all this indicates, one is tempted to ask why are such endowments for astronomical research so scanty in England? I do not think the answer is far to seek. In leaving money to Harvard College Mr. Paine and those like him know that they are providing means for legitimate work of genuine scientific interest, to be carried out by noble and absolutely disinterested workers toiling for the sake of knowledge, like Pickering and his compeers; whereas every scientific man in this country knows full well that the Ring who are clamorous for "the endowment of *their* scientific research" are simply endeavouring to secure a genteel form of permanent out-door relief from the Consolidated Fund. What private donor, with the slightest knowledge of science, would contribute one farthing to the support of such an organisation as the Solar Physics Committee for example?

The next report before me is from the Warner Observatory, in which Mr. Lewis Swift gives an account of the nebulæ discovered there between the years 1883 and 1886, amounting to no less than 540. Shorter accounts of miscellaneous observations also appear, and there are plates and descriptions of the observatory itself, and of the 16in. Alvan Clark equatoreal, which is its chief instrument. Appended to the volume are reprints of the "Warner Prize Essays." The first, on "Comets," by Prof. Lewis Boss, which, as a précis of our existing knowledge of these errant bodies, is excellent, may be held to have legitimately earned the premium conferred upom it. Mr. Boss's essay is succeeded by four on the "After- (and fore-) glows," which created so much discussion in 1883 to 1886. The initial one, by Prof. Kiessling, of Hamburg, contains a quantity of interesting information as to the distribution of colours at sunset and sunrise; the second, by Mr. J. E. Clark, of York, in this country, largely follows Prof. Kiessling; while with the fourth, by the Rev. Sereno Bishop, I have already dealt in these columns. These three essayists seem to have got all their facts and arguments (?) from *Nature;* and write as though the origin of the remarkable atmospheric phenomena they discuss must of necessity have been in the Krakatoa eruption. How people may blunder from confining their references to articles written in one single journal to support a foregone conclusion is evidenced by the fact that every one of these gentry is apparently in hopeless ignorance that Mr. Neison, the Government Astronomer in Natal, was drawing these astonishing after-glows in February, 1883, while the Krakatoa eruption did not happen until the subsequent August. By far the most sensible and scientific of the four essays which secured prizes is that by Mr. H. C. Maine, of Rochester, N.Y., albeit he places more confidence in Prof. Balfour Stewart than he would find any independent English man of science able or willing to do.

Before dismissing American astronomy I may just refer to the excellent work done by Mr. Edwin F. Sawyer, of Cambridge, Mass., in the observation of variable stars; and in the determination of the relative magnitude of the stars between the Equator and 30° S.D. not fainter than the 7th mag., the latter being a revision of so much of Dr. Gould's "Uranometria Argentina" as is included in those limits. Here is another illustration of the perennial value to science of the labours of those who undertake investigations for the sheer love of truth, and who do not approach the eye-end of a telescope making a mental calculation of how much they shall get by it!

I am sorry that your report (on pp. 538 and 539) of the discussion at the Annual Meeting of the Royal Astronomical Society, on the policy of medal-giving, extends to such a length as apparently to have excluded anything but so short a *précis* of the President's address; because I regard that address as a really admirable example of the manner in which a brilliant mathematician can, on occasion, render the most abstruse and technical results intelligible to numbers to whom they would otherwise be an absolutely sealed book. Far be it from me to institute invidious comparisons; but I cannot but feel that it is some time since the dignity and reputation of the Society have been more worthily sustained than they are by the present occupant of the presidential chair.

As one of the "anonymous writers" presumably referred to by Mr. Watson in the concluding sentence of letter 26834 (p. 541), I should really like very humbly to inquire who Mr. Roberts is, that, when he makes a preposterous statement before a large public audience, the utter folly of such statement should be exempt from criticism? I have not the pleasure of Mr. Roberts's personal acquaintance; but had I known him ever so well, I should not have felt that my friendship imposed any obligation on me merely to say smooth things; nor, whatever Mr. Watson may think, should I have altered my language one iota, had I signed my comments *proprio nomine*. A great deal of nonsense has been talked about Mr. Roberts's photographs. They are simply the result of very protracted exposure. If Mr. Common or the MM. Henry choose to expose their plates as long as Mr. Roberts did, unquestionably their results will be equal or superior to his. And I am thoroughly certain that neither of these gentlemen will take pictures of 20 planetoids at a time, 30° from the Ecliptic!

I must ask "Orderic Vital" (letter 26863, p. 546) to wait until I go to London, or otherwise obtain a sight of Professor Harkness's work; which, I regret to say, is not on my own library shelves.

In reply to the latter half of query 61711 (p. 552), any telescope which gave an image of the moon of 20 times the diameter of our satellite as seen with the naked eye, would be said to magnify 20 times. A power of 100 would show Saturn's ring and the snow-cap on Mars (when he is in opposition). An 18in. Gregorian would scarcely bear a higher one. It ought to cost about 15 shillings.

A Fellow of the Royal Astronomical Society.

NOTES ON NEBULÆ.

[26869.]—IN my last "Notes on Nebulæ" (p. 533) may I be allowed to point out a few mistakes which have occurred in the printing?

No. G.C. 880, for "700 than 100," read 200 than 100; also, in footnote to 2851 G.C., for "Duner," read D'Arrest. **Herbert Ingall.**

PHOTOGRAPHS OF STARS—η CASSIOPEIÆ—ALPHA FORNACIS.

[26870.]—IN my reply on p. 198 I did not allude to the engravings in the pages of *Knowledge*, to which Mr. Watson refers in letter 26834, p. 541, as these cannot be considered to be actual photographs. If Mr. Watson will take the trouble to compare, for instance, the copy of the part of Cygnus which appears in *Knowledge* for May, 1886, with the actual photograph of the same portion of the sky obtained by MM. Henry, he will find many minor points of difference between the two.

I am much obliged to Mr. Tarrant (letter 26838, page 541) for his measures of η Cassiopeiæ, though I am somewhat puzzled at his arithmetic, which hardly seems "according to Cocker." The measures of η Cassiopeiæ in the Star Guide are given for January, 1886 (cf. p. ix. of the Introduction), and as η Cassiopeiæ is a binary, it must necessarily happen that my data will be discordant with the later measures. When due allowance is made for this, they accord very satisfactorily with Mr. Tarrant's results.

The following determinations of the magnitude of the suspected variable α Fornacis may be of interest to Mr. Stanley Williams (letter 26839, page 542). Piazzi, $3\frac{1}{2}$ (both catalogues); Johnson (at St. Helena), $3\frac{1}{2}$; Armagh I. (1830-35), $3\frac{1}{2}$; Cape Cat., 1840, $3\frac{1}{2}$; Cape Cat., 1850, $3\frac{2}{3}$; Jacob$_2$ (1852), 5·3; B.B. vi. (1864, 3·0; Cape Cat., 1880 (1878), $3\frac{2}{3}$. These are all meridian observations. The following are determinations made during micrometrical observations:—H_2, 1835, 1836, $3\frac{1}{2}$; Jacob, 1847, 1852, 4; 1851, $4\frac{1}{2}$; O. Stone, 1877, $3\frac{1}{2}$; Howe, 1877, 4; Hall, 1879, 4; Burnham, 1879, 4. It is $3\frac{1}{3}$ in Behrmann's, and $3\frac{1}{2}$ in Houzeau's Uranometria. Mr. Williams's comparison stars seem rather distant, and he does not say whether he applied any correction for atmospheric absorption of light or not. Sir W. Herschel, of course, did not.

Feb. 19. **H. Sadler.**

GC. 2091 — STELLAR PHOTOGRAPHY.

[26871.]—AS I see with great pleasure that Mr. H. Ingall is continuing his most valuable series of papers on Nebulæ, I trust he will allow me to call his attention to the little nebula GC. 2091, in order that he may include it in his working list, as it is now becoming favourably placed for observation. As pointed out in my note on the nebula of 29th May, 1885 (letter 24271, p. 276), there seems a great probability of the little star at $235° \pm 9'' \pm$ being variable, and also a *possibility* of proper motion on the part of the nebula itself from the data furnished by Mr. Sadler in his note on the same subject. It is a very faint object even with the full aperture of my telescope, and I tried vainly during the last season to obtain a satisfactory view of it; but the air was never sufficiently transparent.

Having carefully examined the photograph of 42 M Orionis, by Mr. Roberts, which has caused so much controversy, and being acquainted with the circumstances under which it was sent to the R.A.S., I can most fully indorse the concluding portion of Mr. Sadler's letter. Moreover, the photograph is unquestionably an interesting one (despite the over-exposure of the central part) if only as an example of the wonderful amount of light transmitted by a 20in. mirror in 67 minutes; it also shows an extension of the nebula which, so far as I am aware, has never been previously photographed, although it is shown in Tempel's drawing. Regarding the "asteroid theory," no one who has seen the photograph can for a moment doubt the origin of the lines there shown, and had it not been for the unfortunate speech of the Astronomer Royal for Ireland reported in the Liverpool papers, probably nothing further would have been heard of it. It has always seemed to me a great pity that matters of a personal character should be imported into discussions of this sort, especially when, as in this case, they do not bear directly on the question at issue. It seems, at times, as if the fact that no one is infallible is overlooked, and surely no good end, or lasting gain, to astronomy, will be attained by such a means.

Kenneth J. Tarrant.

Letchford House, Pinner, 19th Feb.

THE EFFECT OF REFRACTION ON STAR DISCS.

[26872.]—I AM sorry to require so much space; but I must beg to be allowed to state that "F.R.A.S.," in letter 26807, has entirely misapprehended the point of my correction.

That I should be foolish enough to imagine (as he supposes) that the effect of refraction upon the shape of a star disc is a measurable quantity, would indeed be, as he elegantly expresses it, "rather a large order"; but I do maintain the position taken up in my letter (26782), and am prepared to prove that the elongation, due to refraction, of star discs in the photograph in question amounts to an appreciable quantity—viz, to 8''.

From the current number of the *M. N. R. A. S.*, it will be seen that this negative was exposed for 67m., from S. T. 4h. 13m. to 5h. 20m. The R.A. of θ Orionis is about 5h. 29m., the exposure therefore was begun when the nebula was 76m. E. of the meridian, and concluded when it was nearly due S.

The meridian altitude of an object in Dec. − 5° 30', for latitude 53° 30·5', is 30° 59·5', and its altitude at 19° E. is 28° 51', and the elevation due to refraction in each of these positions is about 96'' and 104'' respectively, and the difference of these two numbers, 8'', is the quantity, to which I referred, by which the star discs would be elongated in a direction very nearly N. and S., in a negative taken by an *accurate* driving clock, such as Mr. Roberts's Cygnus and Sappho charts show that he possesses, in spite of the accidental stoppage which abruptly terminated this particular exposure, and of the assertion to the contrary of a "Third F.R.A.S." in letter 26788.

As 8'' on the original negative is equal to about the $\frac{1}{200}$in., and on the enlarged proof shown at the R. A. S. meeting to $\frac{1}{40}$ of an inch, it is an appreciable quantity, and is the cause of the very manifest ellipticity in the discs in this particular photograph.

Another Fellow of the Royal Astronomical Society.

LIFE OF THE SUN.

[26873.]—IT appears to be assumed by Sir W. Thomson in his lecture on the Sun, an epitome of which is given in the "E.M." of 28th January, in estimating the probable duration of the sun as a heat-giving body, that the solar radiation proceeds continuously in all directions. What is the ground for this assumption? The heat is said to be dissipated in space; but where does it go to? It does not heat the interplanetary space, as we are assured that that is a vacuum dark and cold, and we may reasonably assume that the solar rays are not absorbed into the inter-stellar space beyond.

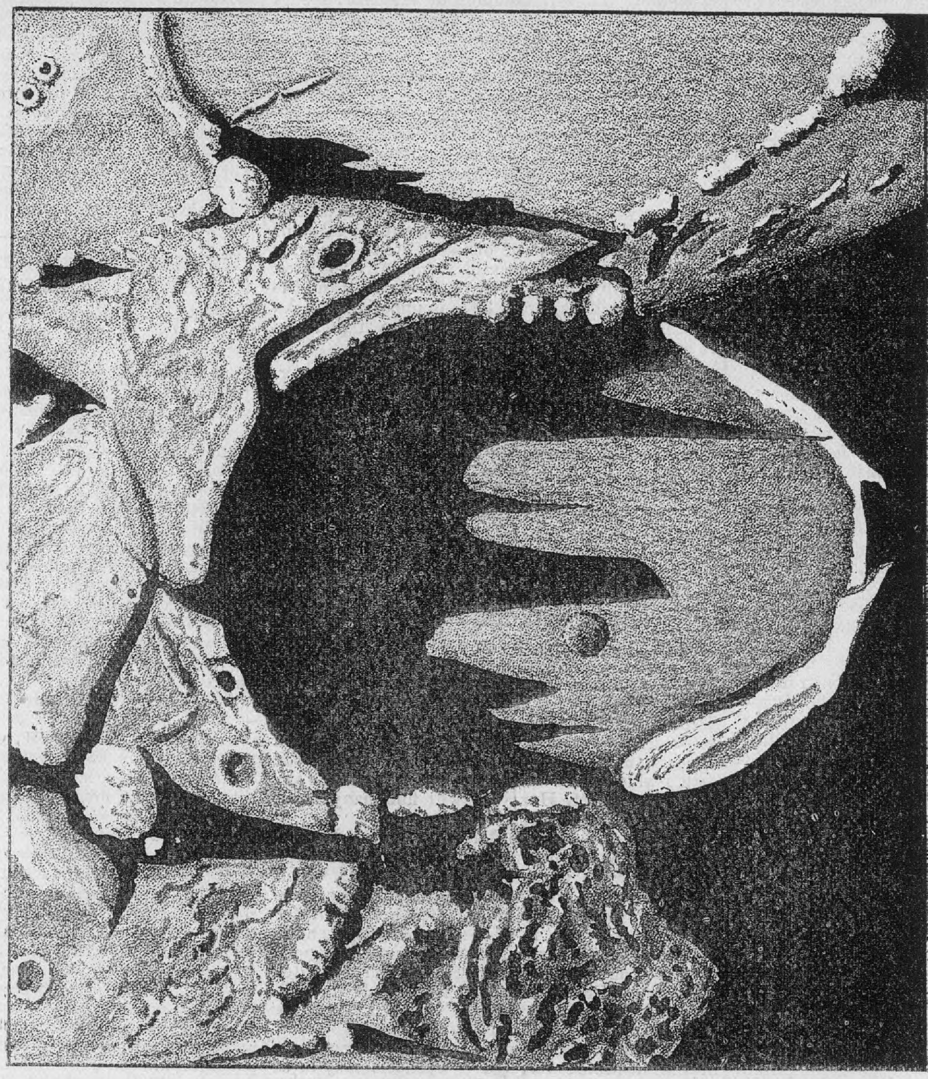
Judging, therefore, by effects, if we cannot account for the disposal of heat otherwise than where it is intercepted, may it not be that the solar rays only break through the dark, cold void to pass to other bodies, attracted thither by the force of gravitation. If this were so, the life of the sun would be practically illimitable.

I only venture to suggest this view, I am afraid, in a very rude form, in the hope that it may produce some argument pro and con. by your scientific readers. **E. T.**

THE LUNAR WALL-PLAIN PLATO —DR. HERSCHEL'S BURNING VOLCANOES—TO "T. C. H."

[26874.]—A SHORT time ago I was asked by a correspondent of "Ours" to give a recent sketch of Plato. Bad observing weather and other hindrances have hitherto prevented me from complying with his request; but the night of February 1st proving favourable, I was able to make the inclosed drawing, which will, perhaps, be acceptable to him and others interested in this remarkable formation, though it by no means includes all the features which a moderate aperture is competent to reveal under the best conditions.

On the evening in question a phenomenon was noted in connection with the shadows of the lofty peaks on the Western wall, which, though occasionally remarked before, has never been satisfactorily accounted for. When they occupied the position shown in sketch (viz., at 6h. 0m.), they exhibited an ill-defined, smudgy outline, strongly contrasting



SUNRISE ON PLATO, FEB. 1, 1887, 6h. 0m.

in this respect with those outside the border, which were clean cut and temptingly measurable. During the past twenty years I have watched the progress of sunrise on Plato very many times; but have only rarely noticed this appearance, the peak shadows, in spite of the dark surface on which they fall, being, as a rule, perfectly distinct when they have retreated as far westward as they are shown in the drawing. I offer no explanation to account for the phenomenon. Hypotheses relating to such appearances are worthless, till we have a wider range of well-authenticated facts on which to found them.

Observations of Plato having been mainly confined to the noteworthy details on the floor, the study of the wall has been, to a great extent, neglected, though no other lunar formation presents a more remarkable and suggestive border—e.g., the wide cleft or valley traversing the south-west rim, the broad gap in the west wall, and the curious depressions on the east wall; but the most interesting feature of all is the great fracture or "fault" which roughly bisects the formation from north-west to south-east, and is marked on the north rim by the intrusion of a massive wall of rock running at right angles to the border, and on the south by a series of breaks or small openings. Traces of this fault may, under favourable conditions, be traced partly across the floor soon after lunar sunrise. The two craters shown a little west of the border were very distinct on February 1st, as was also the much larger object of the same class on the south-west wall. There is a largs shallow ring a little north of this which is not shown in any lunar map.

In reply to "T. C. H." (letter 26812), no one now believes that the volcanoes described by Herchel I. were more than spots on the unilluminated portion of the disc, reflecting, by reason of the nature of their surroundings, a greater proportion of the light received from the earth than other lunar features. **Thos. Gwyn Elger.**

Kempston, Beds., Feb. 12th.

DOES A PETROLEUM LAMP DO WORK?

[26875.]—YES, that it does. Now, I do not wish to pose before your numerous and intelligent readers as a second Newton; but I feel quite arrogant enough to fancy that I have hit upon an idea hitherto unsuspected by everybody living, even in the ranks of science, and that is saying something for an obscure creature like myself. Perhaps, however, I am deluded. not knowing the extent of modern ideas; but as far as my knowledge goes, I am of opinion that the idea of a fire doing work when unobstructed by any boiler is not so very prevalent to-day. The petroleum lamp is such a fire, and if it be true that it does work, then the heat which proceeds forth from the chimney is not the full expression of the energy contained in the oil as generally thought, and which is liberated by combustion. Neither is it. A small portion of the whole energy has been spent in mechanical labour, and escapes, therefore, thermal recognition.

That a lamp does work is evidenced by the gaseous matter moving within the glass. No particle of matter can move without the performance of work, we know. But in what way does the work of a lamp expend itself? Well, we apprehend that it is spent in displacing the atmosphere to suitably accommodate the expansion of a quantity of air that is acted upon by the heat of the lamp. Suppose, for instance, we introduce a lighted lamp into a chamber, having at one side an elongated tube attached, in which works a piston, fixed for the moment, and that the chamber be instantly sealed directly the lamp is in position. Now, after burning one minute, say (provided the air present be sufficient to support it), let us fancy it extinguished. In that chamber now, supposing it to be constructed of non-conductive material, is the whole energy expended by the lamp in that time. Release now the piston, and it rises, and comes to rest when the pressures on either side are equalised. The work now done amounts to the product of the area of the piston into the height raised into the atmospheric pressure on every square inch of surface, plus the weight of the piston itself, in doing which a fraction of the heat disappeared from the vessel. Evidently the lamp performed this work. Now, precisely the same work, we hold, is done by the same sized light in the same time when the lamp is burning upon the table. Fresh supplies of air (the bulk in the form of heated CO_2, if so we are allowed to put it) are continually being raised in temperature to accommodate the ensuing expansion of which the atmosphere is raised up, and becomes charged to a certain extent with potential energy which, becoming kinetic through the impulse of gravitation, succeeds in raising the heated air. As fast as this potential energy is resolved into kinetic the supply is renewed again from the lamp, and thus increments of heat as converted motion are constantly leaving it. Let the lamp stop burning and the atmospheric disturbance rights itself at once. The work of the lamp as manifest to the observer is that portion of the whole work which is represented by the force of the draught, and which is the result of the difference between the weight of the column of air at any instant within the glass, and a similar column externally. That is the amount of displacement in that section of the atmosphere only. But there is potential energy in every other section above, which would continue to raise the heated air if it could be kept together as in a fire balloon. Still, the same stored-up energy continues to raise it when it has left the glass chimney, for it still displaces heavier air that has been lifted up therefore.

We have said enough, perhaps, not to be greatly misunderstood. Now perhaps you will have no objection to me saying that should a more searching explanation of this phenomenon be demanded, it can be found in a sixpenny pamphlet which either myself or my brother (102, Great Lister-street, Birmingham) is now ready to issue forth, entitled, "Science in a Petroleum Lamp." The pamphlet discusses many interesting features.

Bulkington, Rugby. **W. K. Fulleylove.**

MICRO OBJECT-GLASSES.

[26876.]—FOR bacteriological work two lenses are absolutely necessary and a microscope fitted with a condenser. I consider the condenser so important that I would rather have an indifferent lens with a condenser than a first-rate lens without. A cheap and excellent combination is Seibert Nos. 3 and 7—viz., a $\frac{1}{2}$ N.A. ·32 and water imm. $\frac{1}{16}$ N.A. 1·07. These two glasses cost a little under £5, and if you know how to test them you can get two first-rate lenses. A third lens is very useful, as the interval between a $\frac{1}{2}$ and $\frac{1}{16}$ is rather wide. The best lens to put in is a Reichert No. 7a; this is a $\frac{1}{7}$ of N.A. ·84. I think its price is about £2. The next series of three, costing about £9, would be Zeiss A.A., D.D., and G. These are a $\frac{2}{3}$ of N.A. ·31, a $\frac{1}{6}$

N.A. ·82, and a $\frac{1}{9}$ N.A. 1·16. These also require selecting.

Let me caution you against cheap oil immersions; they are usually inferior to cheaper water immersions.

With regard to condensers, Baker fits a hemispherical for 15s., and an Abbé 1·2 N.A. for 35s.

Edward M. Nelson.

THE NEW OPTICAL GLASS OF MESSRS. SCHOTT AND CO.

[26877.]—I MUST remark that the numbers 23 and 26, though occurring among the flint glasses, are, I believe, belonging to the crown glass series; but are placed in the order named because their dispersive power is greater than that of the flint glasses which precede them. This will make the list equally divided between the crown and flint—viz., twenty-two of each.

In will be observed that the above table differs in many respects from those generally given. The aim is to show at a glance the exact optical character of any glass, and I think it answers the purpose remarkably well. In giving the necessary explanatory remarks, I shall try to keep as close as possible to a translation which has very kindly been made for me.

"For the determination of the optical properties of the different kinds of glass, the five bright lines of the spectrum, which can always be easily obtained by means of artificial sources of light, are here employed—viz., the red potassium line (Ka), the sodium line (Na), and the three bright lines of the hydrogen spectrum, $H\alpha$, $H\beta$, $H\gamma$. Since three of these are identical with the Fraunhofer lines C, D, F, of the solar spectrum and both the others, $K\alpha$ and $H\gamma$, lie very near the Fraunhofer lines A and G, these lines in the following pages will be denoted by the letters A′, C, D, F, G′ The wave-lengths of these lines are—

A′ Mean of duble lines	C	D Mean of duble lines	F	G′
0·7677	0·6563	0·5893	0·4862	0·4341

"The results of the spectroscopic measures, which have been made according to the method of Dr. Abbe, have been arranged together for comparison in such manner that the absolute value of the refractive index is given for the D line only; but for the determination of dispersion, the *differences* of the refractive indices for the four intervals, C F, A′ D, D F, and F G′ are employed. The dispersion values corresponding to the accuracy of the measures, are given to five places, whilst the refractive index for D is determined only to four places of decimals.

"Since the interval C F comprises the middle and most brilliant part of the spectrum, the mean dispersion of the different kinds of glass will be sufficiently characterised by it; and by its relation to the value of $n_D - 1$, since the line D lies very near to the brightest part of the visible spectrum, a definite numerical expression for the so-called *relative dispersion* $\left(\frac{\Delta n}{n-1}\right)$ is obtained. In the table, for the sake of brevity, the reciprocal of the latter, indicated by the letter v, is introduced in the column near to the mean dispersion. The whole series of different kinds of glass is arranged throughout according to the amount of this number v, from the greatest value to the least, thus proceeding from the least relative dispersion to the greatest: and as the conditions for achromatising one kind of glass by means of another, are essentially determined from these values and their differences, the optical character of a kind of glass with reference to its achromatising power can thus at once be expressed by that number v.

"The dispersion values for the three intervals—A′D, D F, F G′—furnish an accurate estimate of the character of the dispersion, that is, of the relations of partial dispersion in different parts of the spectrum; and afford the requisite basis for determining the degree of achromatism, attainable by the combination of any two kinds of glass. To facilitate a convenient inspection of the whole, those numbers which are found when the relative partial dispersion is divided by the amount of the mean dispersion for the interval C F, have been introduced beneath the dispersion values in the same column in smaller figures.

"A comparison of these quotients for the two different kinds of glass usually employed—viz., crown and flint, enables us to perceive what is the kind and magnitude of the secondary spectrum, which the mutual achromatising of these two kinds of glass must leave outstanding. A greater value of the first quotient (belonging to the interval A′ D) indicates a relative lengthening of the red—a greater value of the third quotient (belonging to the interval F G′)—a relative lengthening of the blue, in the spectrum of the glass in question. The differences of corresponding quotients for the two kinds of glass thus give the measure of the greater or lesser *disproportionality* of their dispersions; on the other hand, their equality indicates the possibility of an achromatising *without secondary* colour-aberration, provided the values of v in the kinds of glass employed, are sufficiently different to permit of their combination as crown and flint glass. We here call attention to the fact, that for the first time kinds of glass are here offered to opticians, which, along with an approximately equal relative dispersion (or of the number v) show generally *considerable* differences in the relations of partial dispersion (compare, for example, the numbers O. 138 (9) and S. 52 (10), O. 152 (23) and S. 8 (24), S. 7 (28) and O. 154 (29) of the catalogue): and such as give approximate proportional dispersion, along with *considerable difference of mean relative dispersion*, which thus render possible achromatic combinations *without secondary spectrum* (that is, an accurate union of *three* different colours of the spectrum); as, for example, the pairs O. 225 (1) and S. 35 (21), S. 40 (2) and S. 35 (21), S. 30 (3) and S. 8 (24), O. 60 (8) and O. 164 (25)."

I have been induced to give the preceding rather lengthy extract from Messrs. Schott's catalogue, because the arrangement of the optical data is in many respects new, and it seemed undesirable to condense the very explicit directions which are given for its interpretation and use. I shall conclude the present paper with the translation of a note appended to the introduction to the table.

"An accurate investigation of the numbers in the Table leads to the conclusion, that the employment of a much greater number of chemical elements, than have ever previously been used in the manufacture of optical glass, has not introduced, strictly speaking, a proportional dispersion in the composition of the glass of any notably different values of v. In the case of the above-mentioned combinations, which allow of three colours being united, a slight aberration of the blue remains outstanding, when the red is combined with the two middle colours; or an aberration of the red, when the blue is made to coincide with the middle colours; whilst the first and third quotients never simultaneously assume identical values. The *tertiary spectrum* arising from this aberration may, however, be considered as practically eliminated, compared with the great secondary spectrum, which the pre sen available crown and flint, made from the sili cate series, leave outstanding."

This paper and the preceding one will enable the reader to intelligently peruse the new list of glasses for optical work; probably, I may send a few remarks on theoretical matters connected therewith at an early date. **Orderic Vital.**

DR. SCHOTT AND DR. ABBE'S NEW OPTICAL GLASS.

[26878.]—IN reference to some of my brother-readers (letters 26685, "F.R.A.S"; 26796, W. G. Penny; 26759 and 26824, "Orderic Vital") in discussion about Dr. Schott and Co.'s new optical glass, I can inform them that that most eminent optical firm, Reinfelder and Hertel, in Munich, have already made some 5in., 6in., and 7in. double objectives of the new Jena glass, with a very fine result. They give no secondary spectrum—only a tertiary, which is small in respect to the secondary spectrum.

I possess a very fine 5½in. Reinfelder and Hertel refractor with glass from Feil in Paris, which gives a stark blue secondary spectrum. I have ordered a 3¾in. refractor from the same firm, with Jena glass. As soon as I have received and mounted it, I shall give a few words about its performance.

Victor Nielsen.

Copenhagen V., Sofievei 22.

DIPSOMANIA—GRAVITATION.

[26879.]—IN answer to "T. C. H." (letter 26812, page 520), I have heard nothing more of Mr. Edge's case. I should be very glad to give "T. C. H." any help in my power; but I fear I can tell him nothing more than I told Mr. Edge—viz., that "T. C. H." might try to mesmermise his friend himself, and if he fail, try to get some man of firm character and uprightness to do so. If "T. C. H." does not understand how to proceed in the operation, I will lend him a book on the subject, if he will advertise his address, or write to me to "Ordnance Office, Enniskillen." After all, it is but a poor method of curing a man of a vice whereof his own will should cure him.

I should like to say a few words as to the influence of gravitation (*vide* reply of "F.R.A.S." to "W. T. N.," on page 519). Gravitation is the only force which appears to act absolutely instantaneously. It is also the only force as to the transmission of which, so far as I know, no theory whatever has been, or probably will be, ever formed. Lastly, it is the grand force which holds together the whole visible universe, to the furthest telescopic double star. I would ask those, then, who, like myself, believe in the existence of an Omnipotent and Omnipresent God, why should we not, in the universal power of gravitation which we see around us, recognise not only a great law of nature, but an active manifestation of the direct power of God, never resting nor changing, but holding worlds, and suns, and systems in their appointed order, as the great flywheel of a manufactory controls the speed of every pulley and axle in the building. Take away the flywheel, and its source of power, and every wheel and engine will stand still. Take away God, or let Him rest but for a moment in His work, and planets, suns, and systems will fly off into space to wander aimlessly for ever therein. And while the great work of God goes on, are not some of us to be compared to an ephemeral insect which flits about the manufactory in its life of a few hours, and seeing the whirling wheels, thinks that it is their nature to go round, that they have always done so, and always will do so? Nay, more: suppose that the whole work of the manufactory was devoted to securing the life and comfort of that insect and his fellows, and that, nevertheless, they should agree that there was no controlling power behind it at all, and that, because they could see that two pulleys were so connected by a strap that when one went round the other must (which, after all, is as much as we know of light, electricity, or chemistry, and more than we know of gravitation), they should consider that they had solved the whole secret of the mechanism; would we not smile at their folly? Yet, as I understand it, that is the position of a scientific atheist. I am sorry for such. I believe some day they will have to learn by sore experience the source of the power. Meanwhile, I give my theory of gravitation for what it is worth—without apology, for is not the origin of the motion of the flywheel as scientific a subject as the mechanism it moves?

Garrison Gunner.

DIPSOMANIA.

[26880.]—IN reply to letter 26812 (page 520), if "T. C. H." will obtain some rack root, and make tea of it, he will find it a perfect cure for drunkenness. This is said to be one of the ingredients in Epps's curacene, which stops the craving for alcohol. **Reclaimed.**

PRODUCTION OF ALUMINIUM — A CHALLENGE — COTTON-SEED OIL—OXYGEN GAS.

[26881.]—MR. WILLIAM WHITE (letter 26815, page 521) makes the definite statement that metallic aluminium can be deposited from a solution of aluminate of soda by the aid of a current of the intensity of 6 volts. He further states that some years ago he left with the editor of the *Chemical News* a strip of copper with half its surface coated with aluminium. Many years since I myself received a piece of metal said to be electro-plated with aluminium, and it is quite possible that it was to Mr. White himself that I was indebted for it. Unfortunately, I did not convince myself that the thin coating was really one of aluminium. Assuming Mr. White to be correct in his statement, and I am by no means satisfied that he has not deceived himself, how is it that there has been no practical outcome of the invention during all these years? I am not suggesting that a method of depositing a thin film of aluminium has much practical value; but how is it that if a thin film can be deposited by electrical means, that a second film cannot be deposited on that, and a third on the second, and so forth, until any requisite thickness is obtained? Seeing how cheap and abundant the sources of aluminium are, and how cheaply metals can now be electro-deposited by the aid of a dynamo, there is no apparent reason why metallic aluminium should not be cheaply produced, *if*—and it is a big if—the statements made and implied in Mr. White's letter are correct.

To put the claim to a pratical test, I hereby declare myself willing, for one month from date, to buy or find a market for any quantity of pure metallic aluminium, whether produced electrolytically or otherwise, at the rate of 2s. per pound. There is a fair offer to the various claimants to the possession of secret methods of reducing aluminium. Why, with handsome fortunes at their command, they content themselves with written descriptions, and the production of thin films, is a mystery it lies with them to solve.

In reply to "Publicola" (query 61726, page 552), I consider refined cotton-seed oil one of the purest oils in commerce, and admirably adapted for cooking and use as food. It is, indeed, already largely used for these purposes, and I believe is quite unobjectionable. On the other hand, it is an established principle that when a person asks for a certain article, the vendor has no right to palm off on him another and cheaper article without acknowledgment. The unacknowledged substitution of butterine for butter, and of a mixture of chicory and coffee for unmixed coffee, are well-known breaches of the Sale of Food and Drugs Act. The substitution of cotton-seed oil, or a mixture of olive and cotton-seed oil, for genuine olive oil is clearly a fraud of the same kind.

"Oxygen Gas" (query 61759, page 553) cannot be liquefied by any pressure, however great, at ordinary temperatures. Extreme cold is a necessary condition of the liquefaction.

Alfred H. Allen.

Sheffield, February 19th.

AS TO THE DEPOSITION OF ALUMINIUM.

[26882.]—MR. J. BAYNES THOMPSON has kindly supplied me with the following details of his process:—

Solution.—Aluminate of sodium in solution of sodium hydrate, 10 per cent. Aluminium trihydrate may be used, and, if so, a stronger solution of sodium hydrate will be required—say, 12½ per cent.

Electricity.—Any source at six volts intensity. If battery, a six-cell Daniell will do very well.

Positive Electrode.—Iron does well. Platinum may be used; but not carbon, which disintegrates. Whatever is used, it must be larger than negative—at least, double.

Heat of Solution.—150° Fahr.; *not* 500°, as has been twice stated. It is hard to imagine how anyone could make such a mistake; for who does not know that with an aqueous solution in an open vessel 500° is an impossibility? It represents high-pressure steam.

This method is only of use for a thin coating of aluminium. It is too slow for electro-plastic. It is quite as slow as iron from ferrous sulphate, or magnesium from Epsom salts.

Cheshunt, Feb. 21. **Wm. White.**

LUMINIFEROUS ETHER.

[26883.]—IN your No. 1143, p. 542, appear two valuable contributions by "A. X." and "Sigma" respectively, on the "Luminiferous Ether." "A. X." asks: "Why may we not go one step farther, and suppose that these same molecules are capable of taking up and passing on that kind of motion which produces the phenomenon of light, &c.?"

This is exactly the theory which Büchner and other German scientists uphold. In "Force and Matter," p. 79, Büchner says: "All the so-called imponderables, such as light, heat, electricity, magnetism, &c., are neither more nor less than changes in the aggregate state of matter—changes which, almost like contagion, are transmitted from body to body. Heat is a separation, cold is an approximation of the material atoms. Light and sound are vibrating undulating bodies." "Electrical and magnetic phenomena," says Czolbe, arise as experience shows, like light and heat, from the reciprocal relations of molecules and atoms." For these reasons, these scientists define 'force' as a mere property of matter."

To myself, at least, then, it appears clear that whatever the properties or forces of "ether" so-called may be, whether it is ordinary matter in a fourth state, as some call it "ultra-gaseous," or whether it is an unknown element, it must still be "matter" possessed of force or forces.

It seems to me impossible that light and heat could pass from the sun, or other cosmical bodies to the earth, without a "material" intervening and connecting medium. We know also that disturbances in the sun, as observed by the faculæ, stand in direct relations to magnetic disturbances, such as "Auroras" on the earth, so that there can be no doubt that this medium is capable of transmitting to the earth besides heat and light, solar electricity. But, principally, I cannot conceive how gravitation could act between cosmical bodies, unless by or because of this "material" connecting medium, to which we give the name of ether.

The idea of "force" as of something residing somewhere, outside of matter, by itself in vacuo, doing nothing, or of matter devoid of properties and forces, and residing in some other vacuum, having in some occult way, forces "superadded" to it, appears to me "chimerical." On the other hand, "ether" representing the ultimate state of "matter," filling the universe infinitely distended, yet possessed of inherent forces residing in its minutest particles, becoming manifest and phenomenal by concentrations, such as the mutual attraction or repulsion of its atoms would cause, seems to me at once a more natural explanation of the action of "ether," the ultimo ratio of which is, at least at present, beyond the grasp of the finite brain power of man. **F. W. H.**

THE STRUCTURE OF EUPODISCUS ARGUS.

[26884.]—RESPECTING the "white dots" on the inner layer of this diatom (26857), like "T. F. S.," I am of opinion that they are really perforations. I have a slide of "selected" valves of this diatom from Tampa Bay, Florida, where the upper membrane and areolations are worn or rotted away in the central part, thus leaving the inner membrane exposed in the centre. On examining these valves, I find some of them have the inner membrane cracked, and in one specimen, the membrane is higher on one side of the crack than on the other. These cracks run from hole to hole, and not round them as they would do if they were "dots," and, in the specimen particularised, the edges of the cracked membrane, with semi-circular gaps, is very noticeable. Speaking roughly, these holes are arranged in lines radiating from the centre of the valve outwards.

I think if Mr. Nelson examines his diatom again that he will find reason to modify his opinion about the structure of this valve so far as relates to the "white dots."

I am not prepared to follow "T. F. S." in his views *re* structure of "angulation." **H. M.**

VERY LIBERAL.

[26885.]—BY a somewhat curious coincidence, this Jubilee year happens to be the bicentenary anniversary of the first issue of Sir Isaac Newton's much-lauded book "The Principia." Would it not be a graceful tribute to his memory if any competent authority would, for the first time, publish a short essay showing the grounds on which his theory was originally founded, and the facts by which his solar system has been subsequently confirmed?

Although it has been the textbook of all the elementary science now taught in all the schools throughout the kingdom, yet no one, during the last 200 years, has ventured to prove that his theories were based upon facts.

With a view to encourage someone to undertake a reliable exposition of the principles enunciated in "The Principia," I am willing to offer and guarantee a premium of £100 for a complete and conclusive illustration of the truth of the various conditions of the truth of Newton's solar system.

Those who are willing to compete for it will please give me notice of their intention.

Balham, S.W. **John Hampden.**

CONTINUOUS BRAKES ON SLIP CARRIAGES.

[26886.]—A COLLISION occurred at Werrington Junction on the Great Northern Railway on the 14th instant, which directs attention to the use of continuous brakes on the slip portions of trains. The slip portion of the North express became detached, and some platelayers who observed the break-loose waved a red flag. The driver applied the non-automatic vacuum brake, and brought his train to rest, when it was run into by the slip-

portion, which was not worked with any continuous brake. If slip-carriages are to be worked, the brake should fulfil the following requirements:—

1. The driver must have control over the whole of his train (including the slip portion) up to the point of slipping.

2. The guard of the slip portion must (to fulfil the Board of Trade conditions) be able to apply the whole of the brakes so long as his portion is attached to the train.

3. When slipped the continuous brake must be left in perfect working order, both upon the train and slip portion.

4. The guard of the slip-portion must be able to take off and put on the continuous brake upon his portion in order to regulate it in running to the platform.

The train which was examined and worked at the recent Railway Congress at Brighton was fitted with brakes which fulfilled all these requirements, and there can be no doubt that, if the train at Werrington Junction had been fitted with a proper automatic continuous brake, the breaking loose of the slip-carriage at a point where it was not required to be slipped would have applied such automatic brake on both parts of the train, and brought both safely to rest without any accident.

RAILWAY SIGNAL LIGHTS.

[26887.]—THE recent accident at Sedgley Junction on the London and North-Western Railway adds another to the long list of similar cases which have occurred through mistakes in signal lights, both fixed and hand, and confirms the opinion that a white light should not be an all-right signal.

Numerous errors and accidents have been caused by a street lamp on a bridge, a lamp in the window of a house, a white back-light on a signal post, or a hand-lamp carried by a person walking on the railway being considered by a driver as an all-right signal for him to proceed. No such mistakes could occur if the green light were on all lines made the only all-right signal light, and green should not be employed as a back light, as in practice it is often mistaken. The white light can, with advantage be used as a back-light to indicate to the signalman that his signal is "on," and the absence of such back-light that it is "off." So long as white lights are retained as all-right signals, so long, I fear, mistakes similar to that at Sedgley Junction may be expected to occur.

ACHROMATISM.

[26888.]—I AM glad to find that your able correspondent, "O. V.," recognises the necessity of a different formula for the achromatism of an eyepiece to that which is used for a telescope. But he will assuredly find that it is the one which he gave in a previous letter, with a little alteration, which is the *eyepiece* formula, and that the one given by myself—

$$\frac{w_2}{w_1} = \frac{d - F}{f - d}$$

is the telescopic formula, or that for parallel rays.

In your columns, a few years ago, $Ff + (F-d)^2 = 0$, was proposed as the formula for an eyepiece —i.e., for the case in which the image formed by the first lens has to lie in the focus of the second. And it shows that unless F and f have different signs, d is impossible for an e.p.

If I rightly understand his question in letter 26863, I am afraid that the constants in his list cannot be determined by any theory whatever, inasmuch as they must be quantities which must essentially depend upon observation.

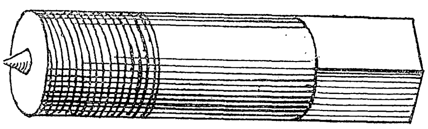
I have unfortunately lost my copy of Airy's Tracts, and can only therefore speak from memory; but I believe he only gives the relative magnitudes of the same star as seen in different telescopes, but not those of different stars seen in the same telescope—e.g., those of Vega and its companion seen in a 3in. glass.

If "F.R.A.S." or "O. V." has seen any formulæ applicable to this latter purpose, perhaps he would kindly give it.

Feb. 18. **W. G. P.**

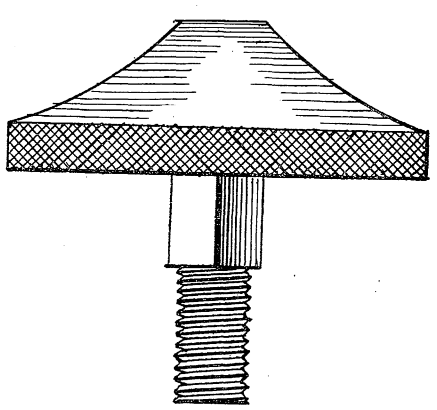
SOME SMALL ADDITIONS TO FACE-PLATES FOR AMATEURS.

[26889.]—FOR a long period I used to think affixing work to my face-plates a tedious and troublesome operation, particularly as regards "truing the centres." I have now succeeded, by a very simple tool, in overcoming my difficulties. I will describe it. Turn a cylinder of very hard wood, preferably pear, about 4 or 5in. long of the exact gauge to receive a screw. My face-plates have a thread of 1in., therefore I finished the cylinder in my case to a trifle over an inch; then I tapped one end for about an inch, so as to fit the screw-hole of said face-plate exactly; at the other end of this wooden plug for about 2in. I removed enough wood to make it square. Its appearance then closely resembled a "plug tap" of extreme length; then in the exact centre of the screw end I pierced a small hole with a hand-drill, and entered a sharp-threaded piece of $\frac{3}{16}$in. steel to the depth of about half an inch. In the lathe this projecting metal point was finished off fine, till it stood only $\frac{1}{4}$in. from surface.



To mount your work, put the square portion full depth into the jaws of your parallel vice, screw up till the plug stands straight and immovable; now take your face-plate, and revolve it on the end screw slowly till you can see the sharp point. Having gauged the centre of any piece you wish to attach to your plate, drill a tiny hole with a hand-drill. You will find your mounted face-plate is turned into a pleasant little table, with all its holes presented to you for action, and great freedom of scope in setting and handling your bolts and nuts. Now place the tiny hole in your piece over the screw-hole, and gently turn the plate till you find the centre point has entered it, taking care to screw back again till the plate and work make exact touch. They will not easily part company, as the little spike prevents a slip. I hope this will prove intelligible, added to the rough sketch.

I have lately added a pair of vice jaw bolts to my largest face-plates; these are well suited to hold pieces of square, oblong, or irregular shape—in the latter case, using lead wedges to block them.



Half-size Jaw Bolts.

I made mine of the best Cumberland soft iron, and then case-hardened them, as I do with all appliances requiring armour.

In a future paper I will tell your amateur readers about other face-plates, and my way of fixing spring centre points, much time and incorrect work being saved thereby. **Eos.**

"THEORY OF MACHINES."

[26890.]—ON p. 490, 6th par., 3rd col., the talented author says: "There are twenty movements which cannot be imitated, &c, &c." The statement is no doubt correct, so far as sewing machines are concerned; but the author has overlooked a very ingenious machine made in Switzerland, and used there and in this country for machine embroidery.

It is too complex to be fully described in a short paper; but in general principle it is a large (about 12ft. long by 8ft. high) square tambour frame, placed vertically, and it is hung in the more massive fixed framing of the machine.

This frame (with the silk, or other material strained as for hand work) is practicable, and is actuated by the manipulator from a pantagraphic action on the left hand of the machine, with the result that the work is moved about the needles, instead of, as in hand work, the needle about the material.

The needles are $\frac{3}{4}$in. long, *pointed at both ends*, and the eyes are in the centre of their length, and they are threaded by girls, just as ordinary needles are threaded. The number for each machine varies with the designs and character of the work. They are placed $1\frac{1}{2}$in. or 2in. apart in the 12ft. length.

On either side of the framing is a horizontal travelling bar, supported at each end on a railway which is fixed at right-angles to the framing of the machines. On the bars at the above-mentioned spaces are fixed some spring clutches, two (one on each bar) for each needle.

These clutches have the action and somewhat the appearance of the thumb and first finger when in the act of pulling something, say a pin, out of a vertical plane.

The operator works the machine as follows:

One of the horizontal bars is drawn as far away from the face of the work as possible, the ready threaded needles are placed in the clutches (one to each) a sufficient depth to be held firmly, the worker makes the bar travel to the work; all the needles enter the work simultaneously and project on the opposite side, the other bar is then brought forward, and the clutches on it are made to grasp the projecting points of the needles. The clutches first in action are then actuated—they release the needles; the bar (and clutches which now hold the needles) is then drawn back; the needles will then have passed completely through the work; the thread is drawn to its proper tension by the action of the bar; the frame is now shifted in position the distance required for another stitch, and the movements just described are repeated, but from the opposite direction, and so on, backward and forward until the work is finished, the whole of the operations being performed by the worker from his seat on the left of the machine. Hand and feet are both used.

Although it is used only for embroidery, two fabrics could be stitched together, but for many purposes would be a waste of time, as a diagram must be made giving the exact form of the stitching required. **W. A. Barber.**
92, Cleveland-street, Feb. 14.

AMMETERS AND VOLTMETERS.

[26891.]—A FEW weeks ago I promised to test and report upon a pair of the above instruments, and have now much pleasure in doing so. The voltmeter was compared with one by Cardew, which has been recently calibrated and known at time of tests to be accurate. The ammeter was compared with one of Siemens' dynamometers newly checked by electro-deposition; the resistances were all measured by a resistance instrument adjusted on Rayleigh ohms from a coil compared and certified at the Cavendish Laboratory:—

MR. BOTTONE'S AMMETER AS SUPPLIED AT 5S.

Current in Ampères Dynamometer.	Current on Ammeter N. W. Quadrant.	Current in Ampères Dynamometer.	Current on Ammeter S. W. Quadrant.
1·66	2	1·47	2
2·43	3	2·05	3
3·40	4	2·62	4
4·17	5	3·35	5

MR. BOTTONE'S VOLTMETER AS SUPPLIED AT 5S.

Volts on Cardews's Voltmeter.	Volts on Voltmeter N. W. Quadrant.	Volts on Cardew's Voltmeter.	Volts on Voltmeter S. W. Quadrant.
1·37	1	1·5	1
2·3	2	2·8	2
3·4	3	4·7	3
4·7	4	6·4	4
5·7	5	8·4	5

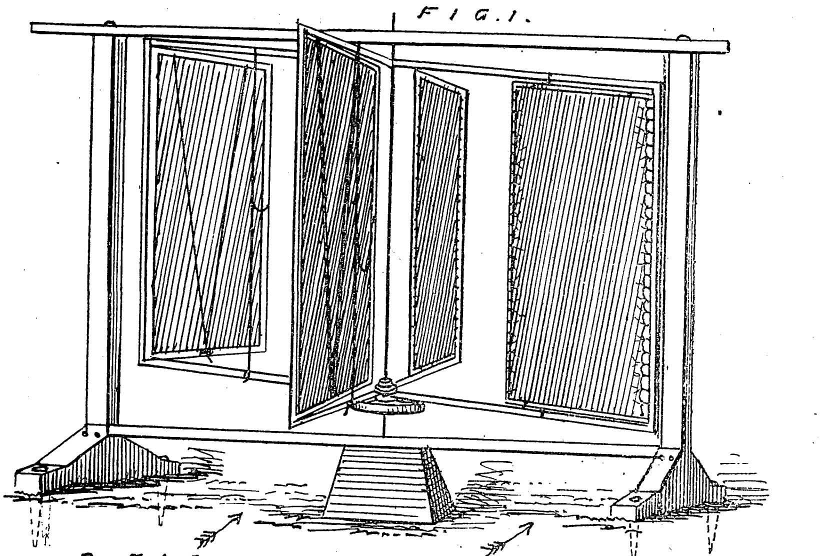
The ammeter is marked as R = ·00034 ohm; I find it has a resistance = ·0045 ohm at 12° C.

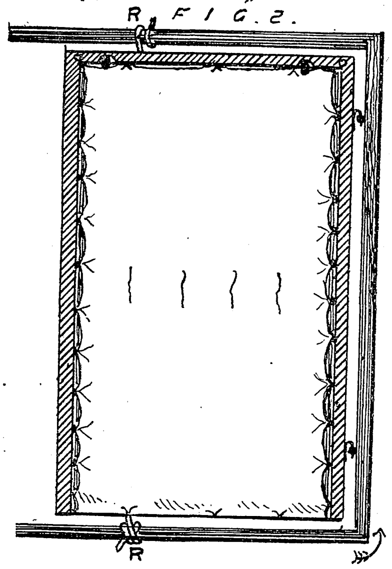
The voltmeter is marked R = 300 ohms; I find it has a resistance = 168·5 ohms at 12° C.

I leave these figures to speak for themselves. I may say that I would have been very pleased had they agreed more closely, as a cheap and fairly accurate meter is much wanted; but I am afraid they cannot be combined. If Mr. Bottone thinks it necessary, I shall be pleased to give him my name; but I think he will accept my results in the spirit in which I give them. **Ohm.**

HORIZONTAL WINDMILLS.

[26892.]—HAVING worked for many years at the subject of windmills, I have followed with great interest the various articles which have lately appeared in your valuable paper, and I was much pleased to see in your last number a descrip-





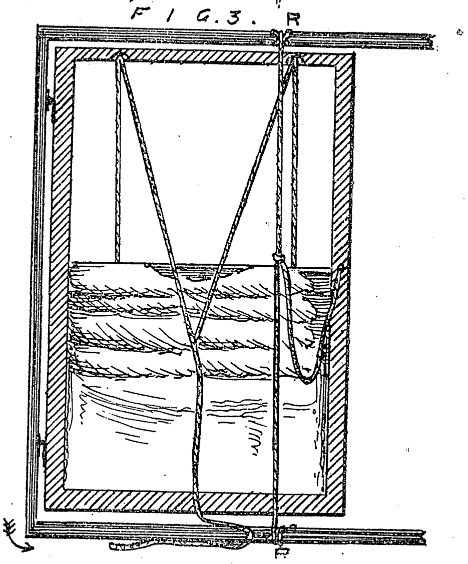


Fig. 1.—General view of Mill in action. Fig. 2.—Sail up to full power pressing against rope R. Fig. 3.—Opposite view of sail run up to half power.

tion and drawing of windmill as made by Mr. Russell.

About a fortnight ago I made a model on the same principle as Mr. Russel's mill, and I venture to send a sketch of one I am making on a large scale, in case some of the points of construction may be of interest to others. The points I have chiefly considered are to avoid unnecessary friction

FIG. 4.

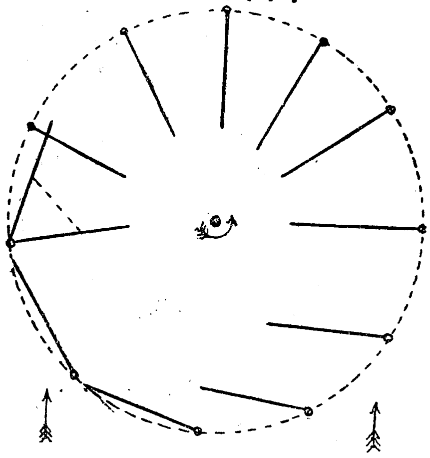

Fig. 4.—View showing position of sail at the different points.

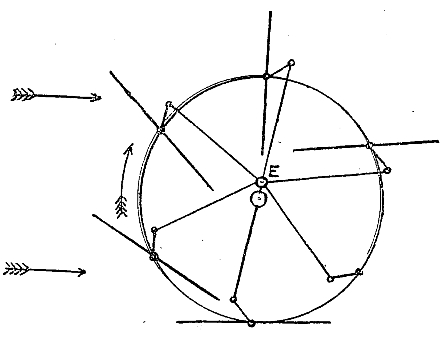
and strain in the running of the shaft; to be able to regulate the amount of sail to the power of the wind, and to prevent a sudden shock when the framework carrying the sail strikes the arms, this latter point being effected by causing the framework to come in contact with a rope, R, stretched between the arms.

I have been working at windmills with the hope of ultimately using them for storage cells, for which I am at present obliged to use a steam-engine. I find it absolutely necessary to be able to furl the sails in a gale, as my last mill was completely destroyed, and it was by watching a piece of the torn canvas streaming from one of the arms which alternately wrapped round and released itself from the axle as the arm rotated, which gave me the idea of my present mill, which in principle appears somewhat similar to that made by Mr. Russell. **W. I. S. Barber Starkey.**

HORIZONTAL WINDMILLS.

[26893.]—I VENTURE to send details of a mill which in model form has given very good results, in the hope that some of our experimenters will give it a trial and report on it. In designing it, it has been my object to so place each sail that at all



points of revolution it shall give off its maximum of power. This it does for seven-eighths of its circumference, the dead point occurring at the back—that is, the lee side.

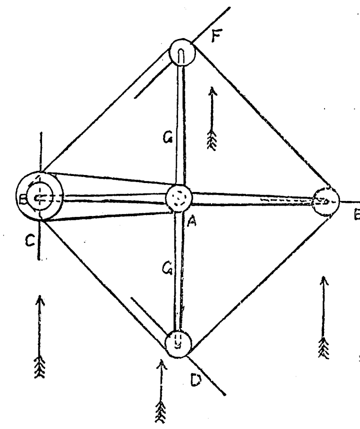
The accompanying sketch will explain its action. A small eccentric operates the striking rods connected with the levers, said levers each being fixed at an angle of 45° with face of sail; a vane on top of mill keeps eccentric always in one relative position to the direction of the wind.

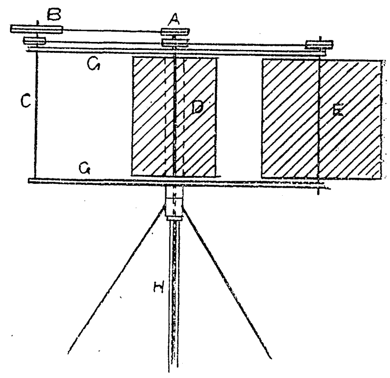
Mr. Vallance has succeeded in running his mill with one sail. Mine will not run with one, but it will with two.

One model ran so fast as to appear solid, at the same time it was perfectly silent. Mr. Wells is advertising these models in the Sale Column, and one of them explains itself better than a page of print. **Geo. Button.**

[26894.]—IN reference to the discussion on horizontal windmills, I inclose a plan and elevation of what I consider one of the best forms of a horizontal windmill.

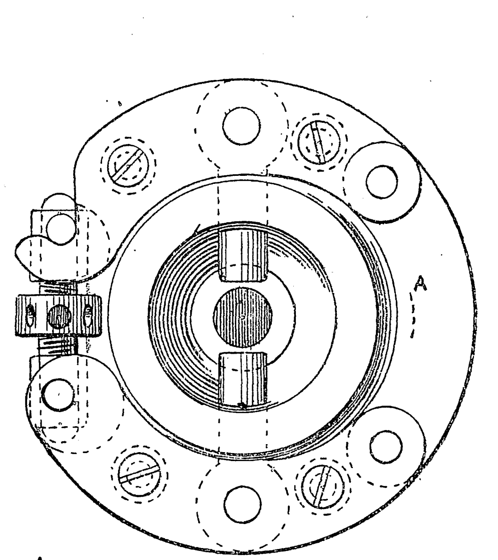
Although there are many ways in which this may be fitted up, I have only given one way in order to show the principle on which it works. G G are eight arms fixed on to a boss, which is a working fit on spindle H. Four arms are fixed on each end of boss at a suitable distance apart; at the extreme end of these arms are placed the four

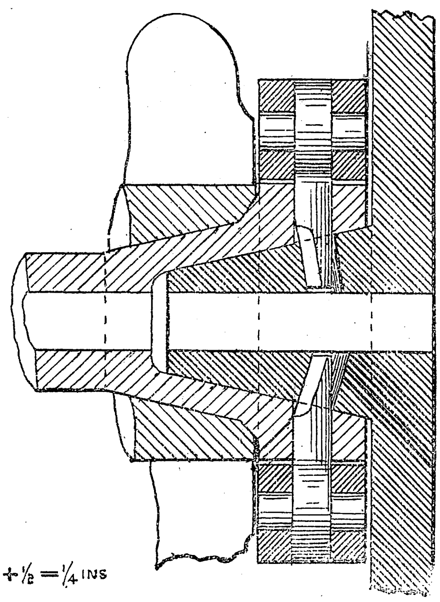




blades C D E F, which blades are kept in a position for getting the best results from the wind by means of gearing of whatever form may be thought best. I have shown it worked with pitch chain for simplicity of explanation. The spindle H is movable, so far that it can be easily shifted to the direction of the wind, either by hand or automatically by a vane on top. On top of spindle is fixed the chain wheel A, which imparts motion to the wheel B, which is fixed on to blade C. B is double the size of A, so that when the mill takes a whole turn the blade takes only half a turn. On blade C, as also on other blades, is fixed another wheel, which is connected by another chain, so that it can be seen, whatever motion is imparted to C, the other blades have a corresponding motion. I think the illustration will explain the rest; the arrows show the direction of the wind. On plan, E is shown at its best power, while F is still utilising the wind, C is coming up against the wind edge on, while D is doing fair work at that point; in fact, the blades commence to do work immediately after passing the point C, and continue to do so until they again approach the same point. **Tul.**

[26895.]—I HAVE been watching this discussion with some interest, and should like to add a few words. I agree with "A. Liverpool," that the idea of a horizontal windmill is not new. Indeed, it is almost "as old as the hills"; it is mentioned in the "Theatrum" of Leopold; and more recently Smeaton exhaustively experimented on them in 1759, and unconditionally condemned them. In his paper read before the Royal Society (1759), Smeaton, on this subject, says, "Observations upon the effects of common windmills with oblique vanes, have led many to imagine that could the vanes be brought to receive the direct impulse, like a ship sailing before the wind, it would be a very great improvement in point of power, while others





A IS A SINGLE LINK: NEEDS CLEARANCE SHOWN ÷ ½ = ¼ INS

attending to the extraordinary effects of oblique vanes have been led to imagine that oblique vanes applied to water mills would as much exceed the common water wheels, as the vertical windmills are found to have exceeded all attempts towards a horizontal one. Both these notions, but especially the first, have so plausible an appearance, that of late years there has seldom been wanting those who have assiduously employed themselves to bring to bear designs of this kind."

The disadvantage of horizontal windmills does not merely consist in that each sail when directly exposed to wind is capable of a less power than an oblique one of the same dimensions; but that in a horizontal windmill little more than one sail can be acting at once, whereas in the common windmill all act together; and therefore supposing each vane of a horizontal windmill of the same dimensions as each vane of the vertical, it is manifest the power of a vertical mill will be greater than the power of the horizontal one. This disadvantage arises from the nature of the thing; but if we consider the further disadvantage that arises from the difficulty of getting the sails back against the wind, we need not wonder if this mill has been found to have not much above one-eighth the power of the common sort.

As regards the mill shown in F. Russell's sketch recently, in addition to the above inherent defects, it would probably thrash itself to pieces in a fresh breeze of wind, and would ordinarily make as much noise as a stamping mill. **J. Q. D.**

[26896.]—WE have been much interested in this discussion; but as there seems little chance of the merits (or otherwise) of the horizontal being proved by discussion only, we have decided to erect one large enough to do useful work. We have begun making it, and hope to have it finished in about a month, and will then send drawing, description, and give results (Editor permitting). Is not the case of horizontal v. vertical mills somewhat similar to that of paddle v. screw? A ship in strong head-wind may have her screw revolving at full speed, and yet make no way; but a paddle under same conditions goes ahead or her engines stop. **B. and G.**

LATHE MATTERS.

[26897.]—THE weak points of my proposed mandrel nose are noticed by "F. A. M." as I expected; but I do not think they are so serious as he puts them.

It never occurred to me, however, that it was complex: then it has the advantage of the screw, it being a simple surface, and in freedom from wear. Further, a screw in spring temper is no easy thing to cut with sufficient truth. The holes in bosses of chucks could be accurately marked off, or drilled through a ring gauge with a flange, to be bolted through hole to pull up to face and fasten. The same Morse drill could be used for all cylindrical holes, and set aside for extras when needed. One gauge might serve several lathes.

It is not quite true that the two cone-points only touch at a *point* each, as the contact is theoretically a line; and the line would develop into a surface of just enough area to stand the pressure the first time the points fixed a chuck. A little might perhaps with advantage be scraped or filed away in the holes in mandrel, on the contact line, so as to leave a double surface. I think their holding power would be sufficient for the purposes of the lathe when the points were made of full-size—as they did not come out in the sketch. They have not to stand back-gear; nor yet the full power of the lathe, as that is given off from the grooved face-plate. If well set, the strain then put on them would be very unlikely to be increased by work in the lathe, even with long over-stands, as the cone would act approximately as a cylinder. However, a plan that has cylindrical surfaces in contact in the teeth and holes, and is more likely to suit, perhaps, as it takes up less room—though it is a little more inclined to number of parts—is appended. It is a neater device than the dog, but is not so easily transferred from one chuck to another when used with a nose on mandrel, also it may affect the oval chuck. In the matter of the tail-stock fastening proposed by self, it occurs to me that a handle on bolt at the back of head would be a handier and better gear than that shown. It would not be so inclined to twist the bolts while slack, and could have a square socket on bolt to stop that tendency; also the handle would be easier to get at towards tail of bed, and the action of bolt end on underside of bed would be nicer and freer from wear. **Vulcan.**

New Small Calibre Repeater Rifle in Denmark.—The Danish War Department has for same considerable time been directing its attention to a small calibre rifle, and a series of experiments have taken place with this object in view. The result is giving great satisfaction. The department have not only succeeded in producing a thoroughly satisfactory repeater model, but the difficulties from the small calibre have been satisfactorily overcome, and an 8-millimetre cartridge, has been adopted. By coating the leaden ball with copper, and by pressing the powder in the cartridge a velocity of 150ft. above that mentioned by the Austrian Minister of War has been obtained. There is no depositing of lead in the barrel, and the wear and tear from a bullet coated with copper is of course very small. The accuracy of the shooting continues unaltered without cleaning the barrel—even when as many as 50 to 100 shots have been fired. The accuracy of the fire is proved by the fact of more than half of the shots at a distance of 1,200ft. being covered by a belt about 6in. broad, and the distance between the highest and the lowest hit being only about 8in. as far as half the shots were concerned. At a distance of 3,200ft. this figures were only increased to 2¾ft. and 2⅝ft. respectively.—*Engineering.*

Coal in the Southern States.—Coal covers an area of 5,000 square miles in Tennessee, with from one to three workable seams, the best coking seam being the Sewanee, which is 500 square miles in extent. In Alabama it covers an area of 6,000 square miles, embracing the Warrior, Cahawba, and Coosa fields, with three or four workable seams each from 4ft. to 7ft. in thickness, and mostly coking coal. Of these the Pratt seam has hitherto furnished by far the greatest amount of coal; but the good coking qualities of the other veins have been proved. The production of the Pratt mine is now 2,500 tons per day, and that of the Sewanee mine 1,500 tons per day.

THE rage for high towers has now taken effect in Belgium, and a design for a wood tower of Flamboyant type, and 300 mètres in height, has been made by MM. F. Hennebeque and E. Néve, and proposed for erection in connection with the Brussels Exhibition of next year.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.***

[61059.]—**Photography (U.Q.)**—The angle covered by the Dallmeyer R R is about 60°. The "Rectigraph" I have no knowledge of; but no doubt it is on the usual rectilinear or symmetrical lines, and most probably useful. The process recommended by Schnauss is something like the patent (lapsed) process of Kennett, and by it excellent results no doubt can be obtained, as with the old Kennett pellicle perfect plates could be produced with the very slightest effort.—G. J.

[61124.]—**Analysis of Lime (U.Q.)**—The details of the process mentioned by Lunge are not given in the query, and I have not the pocketbook to refer to. I presume that the lime is to be suspended in water and then titrated; if so there is little reason to wonder at the reappearance of the pink colour of the phenol-phthalein, simply because the lime not being nearly all in solution, but mostly in suspension, the acid does not act on its particles instantaneously, the more so because of the insolubility of the calcium oxalate which is produced, and which therefore forms a protective coating round them. Thus the indicator may show that the acid has been added in excess, when as a matter of fact there is still plenty of free lime; this coming slowly in contact with the acid neutralises it and reverses the colour of the indicator. Moreover, the process depends on the indicator used (either litmus or phenol-phthalein) being *quantitatively* sensitive to CO_2. Litmus is certainly not so, nor, I think, is phenol-phthalein—not quantitatively, that is. If my supposition that the method is as I have stated be correct, it is quite untrustworthy. The best way to determine the amount of free and carbonated lime in a commercial specimen would probably be as follows:—A known weight is dissolved in a known quantity of saturated HCl or HNO_3, which is in excess of that necessary for neutralising the whole of the lime, and the excess of acid determined by titrating back with standard alkali, either carbonated or caustic, using methyl orange as an indicator. This gives the total lime, caustic and carbonated. Another portion has its CO_2 estimated by means of the calcimeter, thereby providing the rest of the data requisite.—BERTRAM BLOUNT.

[61236.]—**Colliery Winding Engines.**—In reply to this query, it is impossible to give the desired information without some further particulars. Owing to the peculiar circumstances under which colliery winding engines have to work, the use of steam will not be so economical as in an ordinary stationary engine; but, generally, I find the point at which steam in winding engines is cut off is about two-thirds of the stroke.—G. WORLANDS.

[61131.]—**Electric Cautery — Bottone's Ammeter.**—The instrument forwarded to me by Mr. Bottone is, according to the letter which accompanied it, the "very one" tested by Mr. Conry, and reported upon by him in your issue of the 11th inst., and one which is so highly valued by Mr. B. that he uses it "as a test instrument wherewith to calibrate others." In the original query (Dec. 10) I asked for the means of measuring with scientific accuracy—not roughly—the current employed to heat my cautery. I append the results of a careful testing of the above instrument, leaving your electrical readers to judge whether the requirements of my query are met by this instrument or not:—

MR. BOTTONE'S 5S. AMMETER.

The readings on the instrument, 90 from zero to 5 on each side.

Value on Right.	Figures on the Instrument.	Value on Left.
8·00	5	6 88
6·3	4	
4·5	3	
3·1	2	2·82
1·482	1	

Resistance marked in pencil on bottom of instrument .... = 0·00034
Resistance determined .... = 0·0063

—A. DUNLOP STEWART, M.B.

[61131.]—**Electric Cautery.**—I was rather surprised to see in issue of Feb. 11 *re* Mr. Conry's test of the Bottone ammeters that the scale is graduated to 1/10 of an ampère. I got an ammeter and voltmeter about two months ago, and there is no division under 1 ampère or 1 volt. Would Mr. Bottone kindly explain why he says they are calibrated to tenths, and yet when I buy one I find only units on the scale? Mr. Conry's test merely

seemed to show the sensitiveness of the instruments; but it does not appear if he tried whether the scale was actually right. Besides, the moment of the needle is apt to change, and this throws the graduation out. A few tests a medical electrician made with me the other day may be of service generally. Platinum wire heated in air till fully red-hot and fit for cauterising.

Dia. in mm.	·42	·63	·53	·73	·44	·49	·74
Current in ampères	7	22	12	20	7·5	10	22

There is something peculiar about the ·63 wire; the current registered is abnormally large. I think it was impure—at any rate, it took 22 ampères to heat it red-hot. I may be allowed to point out that a formula into which resistance of cautery enters is of no use, as for every temperature R varies, and also the radiation of heat is different in air, and in a tumour, &c., to be operated on. It would be interesting if Dr. A. D. Stewart would tell us if he has found his way out of the difficulty, and what means he now uses to work his cautery. —IOTA.

[61250.]—**Telescope O.G., &c. (U.Q.)**—The lenses, if placed 4in. apart, would make a doublet of 26in. focus, the rule being to multiply the focal length of one lens by that of the other, and divide by the sum of their focal lengths, less the distance in inches apart, thus: $\frac{62 \times 42}{104 - 4} = \frac{2604}{100}$ = say 26. It is probable that there would be considerable difference between the visual and chemical foci, which could be determined by experiment; but altogether I think you would get better photographs by using a Lancaster single lens, having regard to the great focal length of the combination, as it would necessitate a camera about 3ft. pull of bellows.—G. J.

[61291.]—**Ageing Wood Carvings.**—I had hoped our mutual friend, Mr. S. Bottone, would have picked this up; but, as he has not, I am afraid I cannot be of much assistance to you. It was not mentioned at time query was asked what wood was used. As it now appears cypress wood was selected, it is questionable if any amount of fuming will give a really satisfactory result on account of the small amount of tannin it contains. When it is desired to produce any fumed work, it is necessary to be careful in the selection of the wood, which is nearly always oak or mahogany (the former preferred). There is even a great difference in samples of these woods, some assuming the desired shade after about two hours' exposure in the fuming-box, while others require two or three days, or even a week. Very often, when satinwood is to be used, and there is plenty of time, the wood is "got out" for the job—"jacked" over, and stood in a loft immediately over a stable to dry, remaining there sometimes for months. The ammonia rising from beneath causes the wood to assume a lovely rich colour. I have made many inquiries from experienced men, and have been unable to learn any dodge likely to be of service to you, and would, therefore, suggest you expose your tracery-work in a closely-confined metal box to the strong fumes of ammonia for, say, a fortnight, or as much more as convenient. This is all, I think, you can do other than staining, which you say is objectionable in your particular case.—S. BRETTON.

[61300.] — **Saccharine.** — I am obliged to "F. I. C.," p. 525. I have since had a chat with a medical man, and he (and others) have explained that the action of taste by the tongue is due to some nerves not in the posterior third thereof. The posterior third of the tongue is not affected by sweet or bitter, so the doctor says. Now that I know more of the action of tasting (what I do know, however, is little enough), I am not so much surprised at a substance which passes inertly (unchanged) through the system, yet causing the sweet taste. Perhaps "F. I. C." will expand.—R. S. T.

[61347.]—**N. E. Locos. (U.Q.)**—As this query has remained unanswered, I send the following particulars of Mr. Worsdell's compound goods engine:—H.p. cylinder, 18in. diam. by 24in. stroke; l.p. cylinder, 26in. diam. by 24in. stroke; diameter of wheels, 5ft. 1¼in.; wheel base, leading to driving, 8ft.; driving to trailing, 8ft. 6in.; total, 16ft. 6in. Boiler contains 203 tubes; length, 10ft. 11½in.; outside diameter, 1¾in. Heating surface: tubes, 1026·12sq.ft.; firebox, 110sq.ft.; total, 1136·12sq.ft. Grate area, 17·23sq.ft. Working pressure, 160lb. Weight in working order: on leading wheels, 14tons 3cwt. 2qr.; on driving wheels, 15tons 10cwt.; on trailing wheels, 12tons 3cwt.; total, 41tons 16cwt. 2qr. The valve gear is Joy's.—EAST ANGLIAN.

[61377.]—**Arc Lamp.**—The wires in main and shunt coils vary even in lamps of the same make; had you described the make of your lamp, you might have received more assistance. As a rule, the current in main increases as the carbons approach, and this increase should stop the approach of the carbons, at the same time the current in shunt should decrease, and so allow brake to go on and stop feed, or if a solenoid lamp the weak shunt is overpowered, and the main pulls the carbons apart. The R. of main should not exceed ·02 ohm, and the wire may be of any diameter—not less than ·120in. for a lamp carrying 15 ampères. The series coil should have a resistance not less than 200 ohms, the wire about ·013in., and this may be of either German silver or copper, according to the power required. If only to pull a brake off G.S. will do; but if a solenoid lamp, then copper will be required. When working with incandescent lamps, if the dynamo is compound wound, then your lamp will not regulate unless you include about half an ohm of resistance in series with it. This resistance may be made of iron wire ·1in. diameter, wound on iron mandrel about 1½in. diameter; this will carry the current you name without undue heating.—OHM.

[61387.]—**Ferrule Machine.**—This query is not sufficiently explicit to meet with a full answer. How are the ferrules to be made, and of what shape? One would think that the simplest way would be to cut up solid-drawn tubes into suitable lengths; but as no mention is made of brazing the pieces of hoop iron, it is possible that the ferrules are made by lapping.—E. G. M.

[61392.]—**Electric Motor.**—This querist apparently wants an electric motor to suit a flywheel he has by him. He knows, I suppose, that full directions for making motors have been given many times.—T. J.

[61401.]—**Oval Chuck.**—Should not this querist at least give a reference to the No. of the "E. M." in which he found the chuck he has made? That there is a "curious twist in the work" produced may be due to the fact that it is not properly mounted; but it is impossible to suggest what is wrong on the bare statements made by the querist. —C. L.

[61402.]—**Electric Bath.**—Is not this rather a peculiar query? Here is someone who has an order to fit an electric bath, and by his own words confesses he knows nothing about it. If he can fit an ordinary bath, that will do quite as well, and he can amuse the patient by connecting a voltaic battery to the bath, one wire to the metal and the other to dip into the water.—ANSER.

[61404.]—**Medallions.**—If the querist cannot say whether his medallions are of plaster or clay, it is only guesswork to try to help him. I am afraid there is no remedy that would not also destroy the surface. The best thing he can do is to size and paint, or cover with one of the bronzes. If of plaster, he is not likely to get them white again.—NUN. DOR.

[61415.]—**Pellet's Process.**—Would not this querist be more likely to obtain an answer to his question if he indicated where an account of Pellet's process is to be found, or at least gave an idea of the frame?—NUN. DOR.

[61426.] — **Charcoal for Small Forge.** — If "Amateur Blacksmith" means charcoal from coal, he can make it only by constructing a coke oven, or a coke mound, which consists of a central chimney around which the lumps of coal are laid with horizontal flues, the whole being covered thickly with slack. If the querist has never made any on this plan, he will find it more economical to purchase what he requires—unless he lives in some altogether inaccessible place. If he means wood-charcoal, that is comparatively easy to make by building a pile of wood and covering it with earth —the object being to char the wood throughout without admitting more air than is necessary. If he will state definitely what he wants, I will see if I can help him.—SAML. RAY.

[61430.]—**Colouring Statues.**—There is one simple way in which "E. X. P." can answer his own query and satisfy himself. Let him take a plaster cast, size carefully twice, or soak it in melted size. When dry, let him paint it with any colour he fancies, mixed with oil and turps, or with size, as he pleases. A small 3d. bust will be amply large enough to show him the effect produced by half a dozen different pigments or mixtures, and when he finds the one he likes best, he can start on the Venus.—NUN. DOR.

[61436.]—**Petroleum Tank.**—Surely it does not "smoke," but visible vapour rises from it. Perhaps the oil has still some of the lighter naphthas in it, as the fact that it throws a yellow scum (vaseline) indicates that it has not been thoroughly refined. If it is petroleum, that alone would account for it; but I have assumed that the querist really means burning oil.—NUN. DOR.

[61437.]—**Influence Machine.**—The vulcanite discs would do for the purpose; but it has been stated that glass is better for any kind of electric machine. No doubt the special discs in question would be better used in making ordinary plate machines.—J. C. R.

[61440.]—**Emery Wheel.**—The power to be obtained from a "5ft. hand-wheel" being an x quantity, it is not possible to do more than advise your correspondent to try narrow emery wheels of small diameter.—NUN. DOR.

[61442.]—**Weight of Moist Air.**—Does not the barometer (mercurial) show us that dry air is heavier than damp air? As a fact, the dry air supports the longer (higher) and heavier column of mercury—at least, is it not the fact? Also that when it rains, the air presumably then damp, or having moisture in it, supports only a shorter column of mercury. Some years ago I had the reason explained to me, but I have forgotten it: I have not time to refer to books. "Milverton" does not explain it. Will somebody do so?—R. S. T.

[61452.] — **Electrical Apparatus.** — I must gently, but firmly, protest against the assertion of Mr. W. Habgood that "secondary batteries can be charged by means of a primary battery for lighting to advantage." The cost of lighting anything beyond a single lamp or so by primary batteries is comparatively heavy, and the cost of lighting through secondaries charged by the primary is such as none but a wealthy amateur would care to incur. With an ordinary primary battery it takes about a week's charging of accumulators to get two or three hours light out of them; also the loss of solution to which he alludes as being inseparable from primaries owing to fall of E.M.F. is easily avoided by simply working the battery regularly day after day when the half-spent solution is reconverted into saturated or full-proportion solution by the addition of fresh chemicals, thus requiring one-half the expenditure that would be necessary to make full-strength solution from plain water, so that nothing need be wasted.—EDWARD CONRY.

[61452.]—**Electrical Apparatus.**—If I am not mistaken, the formula given last week is the same as one given in a pamphlet issued by some interested parties desirous of floating a battery company, and when they prove to their own satisfaction that they can supply the electricity for nothing and still make a profit, such an arrangement comes up regularly; but somehow the thing won't work. I am afraid that we have yet to obtain such lamps as mentioned—viz., giving 1c.p. for four watts, while using accumulators. My experience is that the best lamps in the market require about 3·7 watts per candle-power actual, and if we allow an efficiency of 60 per cent. (which I find is nearly correct in actual use) for accumulators, then we require over 6 watts per c.p. I may add that the lamps usually supplied as 20c.p., and taking at the best 60 watts, are really only 16c.p. While on the subject of lighting from primary batteries, I notice that in "Ours" of Feb. 11, p. 518, Hospitalier puts the cost at 2d. per 10c.p. lamp per hour. This, I believe, does not include labour.—OHM.

[61474.] — **Silver Chloride Cell.**—Jamieson says: "The internal R. of these cells increases on standing by adhesion of oxychloride of zinc on the rod. Frequent use or scraping the rod keeps the R. normal. About 15 minutes of short circuiting is required to bring the full current out of a new cell, and a few seconds that of one in use.—OHM.

[61474.] — **Silver Cell.** — TO J. PEYTON DAVIES.—Please read my reply through. If your cells are spoilt by a 20 minutes' run as you say, they must be of very faulty construction and exceedingly small. It must not be concluded that because your cells are half spoilt by 10 minutes on short circuit, that I am wrong. You had better refer to what Mr. De la Rue says about them.—C. D. R.

[61518.]—**Gas-Engines.**—To J. MC G. AND S. —I quite agree with what you say; but the thing (like the speed of dynamos), is limited by practical considerations. The heat, in my judgment, should not go over 50°. I will write more fully next week.—EDWARD CONRY.

[61519.]—**Mechanical Piano Playing.**—In No. 1,142 Sanderson offers a method for accomplishing this. May I ask him to be so kind as to fulfil his promise?—PERCY SMITH, Rugby.

[61529.]—**Mathematical: Measurement of Drums.**—My best thanks are due to Col. J. R. Campbell for his replies to this query. I should, however, very much like to have a formula in which an inch is taken as the unit of measurement, since in some cases the rope (generally steel wire rope) is of small diameter.—E. M.

[61548.]—**Shipbuilding.**—I am afraid "Video" has not given "Novice" much satisfaction in his answers to the latter's questions, which are perfectly correctly put. I understand "Novice" to ask, What is the engineer's part in getting a ship ready for launching? After the centre-line of the shafting has been fixed, the stern-post is bored to take the stern-tube by means of a portable-engine and large boring-bar supported on suitable brackets. A stage is erected round the stern of the ship for this purpose. The stern-tube itself is a massive casting bored out, "Video's" remarks notwithstanding, for a distance of 3ft. or 4ft. at

each end to take cast-brass bushes, which are usually cast with recesses, in which are put strips of lignum vitæ about 3in. broad. Brass liners are shrunk on the tail-shaft and turned to run in these bushes. These bushes are lubricated by the water which is allowed to pass in between the strips of lignum vitæ. The engineers also fit the sea-cocks and discharge and suction outlets and valves on the ship's side, some of these being below the water-line. A ship is generally launched with tail-shaft and propeller in position.—C. E. A.

[61548.] — **Shipbuilding.** — Many thanks to "Video" for the trouble he has taken in my behalf. As he shrewdly suspects, the question is verbatim from an examination paper. My own impression is that an error has arisen, and that the question should really stand "Describe method of boring out body post boss, &c." The question staggered me, because, as far as I knew, this has always been done previous to erection of stern frame; but my experience has only been with short vessels—screw tugs. "Video" says the hole is afterwards trued out to the lines of machinery, when tube is permanently fitted. Will he add further to my obligation and give *modus operandi* and description of tool used? Surely some of "ours" will give a description of launching an iron steam-ship. I don't think our Editor would think it "too technical" for the columns of a journal confessedly the organ of mechanical science; and I believe such a description would be read with interest by many who have not opportunities of visiting a shipyard.—NOVICE.

[61551.]—**Flow of Water in Pipes.**—My reply to this query has not been inserted, though sent almost a fortnight ago. I presume it did not reach you, so I repeat it. An 18in. pipe at a trifle flatter gradient than 1 in 20 would do the work of a 24in. pipe 1 in 100. The following would also give the required discharge:

A 21in. pipe	1 in	50.
„ 22in.	„	60.
„ 27in.	„	180.
„ 30in.	„	300.

—W. J. TAYLOR.

[61551.]—**Flow of Water through Pipes.**—Many thanks to "Elag" for his explanation. I now send another way of getting at the same result which may be useful to your readers.

Let G = discharge per minute,
H = head of water in feet,
L = length of pipe in yards,
D = diam. of pipe in inches,
} For larger pipe.

$$\text{Then } G = \sqrt{\frac{(3D)^5 \times H}{L}}.$$

Let G^1 = discharge from smaller pipe, and small letters to represent as above—

$$\text{Then } G^1 = \sqrt{\frac{(3\,d)^5 \times h}{l}}$$

but G must $= G^1$.

$$\therefore \sqrt{\frac{(3\,D)^5 \times H}{L}} = \sqrt{\frac{(3\,d)^5 \times n}{l}}$$

$$\sqrt{\frac{(3 \times 24)^5 \times 1}{33\frac{1}{3}}} = \sqrt{\frac{(3\,d)^5 \times 1}{6\frac{2}{3}}}$$

$$\frac{(3\,d)^5}{6\frac{2}{3}} = \frac{(3 \times 24)^5}{33\frac{1}{3}};\ d^5 \times \frac{24^5}{5}$$

$$d = \frac{24}{\sqrt[5]{5}} = 17{\cdot}39 \text{ inches},$$

which is near enough for all practical purposes to "Elag's" result of 17·35in.—ST. GEORGE.

[61554.]—**Darning Machine.**—I am afraid I cannot be of much use to "T. F. S. T." in getting one of these machines. I picked mine up quite by accident; going to an ironmonger's for some old brass, and while looking for some, I came across the machine which was in a very rusty condition, with a lot of needles broken. As I had never seen one before, I bought it and cleaned it up. Seeing the date (patented 1876) on it, I looked at my old MECHANICS of that date, and saw it was advertised by some people at Liverpool. I wrote to them for some needles, but the letter was returned, they having evidently moved. The machine is far from satisfactory, the chief difficulty being the breaking of the thread.—F. C. A.

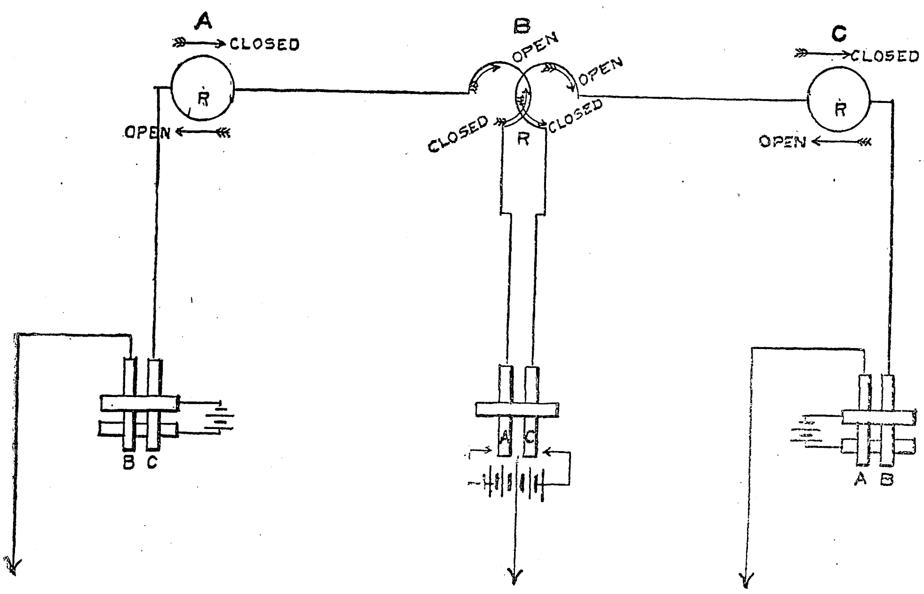
[61560.]—**Engineering.** — "J. H." does not write from the employers' point of view, but from that of a foreman who has had a good deal to do with pupils. I may say that I have had no knowledge of the "look, but don't touch" style of training," and, therefore, deem it something exceptional; but can only repeat what I have already said, that if a pupil wishes to learn he can always do so. Employers, foremen, journeymen will always, so far as my experience goes, render necessary aid to those who seek it in the proper way; otherwise how is it that in the same shops some pupils will go through their whole term and be no good at the finish, while others will be so useful in all departments in turn that their leaving will be rather a matter for regret. Those who assume social superiority, and decline to lend a hand in dirty and hard tasks, will never learn. Rough work, like all work in its earlier stages, must be monotonous at times; but we all get past "the wearisome bitterness of our learning," and, so far from being "unedifying," we regard it afterwards with triumph. Why should a pupil be exempt from a taste of that toil which the workman has to do all his life long? In old times masters could work with their men; now, alas, there is often a deep gulf of alienation between the employer and his hands which a closer intercourse in early life might do something to lessen. An old employer of mine went through his seven years of pupilage, working his ten hours a day like the men with whom he mingled. As a consequence, he, as a master, was equally at home in any department ever after, and all his men knew it, and respected him accordingly. If a pupil works hard and intelligently, without grumbling at the tasks given him, whether distasteful or not, forgets differences in social position while in the factory, makes himself popular, and keeps his eyes and mind open, there is no fear of the issue.—J. H.

[61574.]—**The Calculus.**—The difficulty found by "Another Tyro" may be explained by simple rule of three, thus: If a space expands $\triangle y$ square feet in $\frac{\triangle x}{3}$ seconds, how much will it expand in one second? By rule of three we get the following: $\frac{\triangle x}{3}$ seconds : one second : : $\triangle y$ square feet: the anwer is evidently $\frac{3\triangle y}{\triangle x}$ square feet. Of course during the infinitesimal periods of time the expansion is supposed to be uniform. While on this subject, I would like to say a word to the original "Tyro" about certain difficulties that he mentioned. I think the best way of considering a differential coefficient, at least for a beginner, is to treat the equation between x and y as that of a curve; then the differential coefficient at any point of the curve for a given value of x is the trig. tangent of the angle which the geometrical tangent line at that point makes with the axis of x; for instance, take the equation of $y = x^2$, which we have already had to do with. Now if the axis of x is horizontal, and that of y vertical, this equation will represent a parabola whose vertex is at the origin, its axis corresponding with the axis of y, and distance from vertex to focus $= \frac{1}{4}$, and hence (from conic sections) the horizontal line from the focus to the curve must be $\frac{1}{2}$; also the tangent line at this point must be 45 and the trig. tangent = 1. Now compare this with the equation $y = x^2$; from this we get $\frac{dy}{dx} = 2x$, and if we take $x = \frac{1}{2}$ to agree with the focal line in the parabola, the differential coefficient = 1, and in all cases the differential coefficient will agree with the trig. tangent; and so also for the 2nd, 3rd, &c., differential coefficients. For instance, suppose $y = x^4$, the first differential coefficient will be $4x^3$; put $z = 4x^3$, and suppose this curve to be plotted, then we may differentiate again, and say $w = 12x^2$, and so on, getting a succession of curves, and thus, I think, getting some tangible idea as to the 2nd, 3rd, &c., differential coefficients.—M.I.C.E., Bath.

[61574.]—**The Calculus.**—The fact is, the difficulty which "Tyro" imagines to exist in the meaning of successive differentiation does not really exist, at least in the manner he conceives it, and he seems only to be put astray by confused ideas on the relation between abstract and concrete quantities. It would be of advantage towards avoiding difficulty of this kind if it be borne in mind that algebraic quantities—even negative and imaginary ones—always represent numbers. This generally-received view has, indeed, been combated by at least one very distinguished mathematician, Dr. G. Peacock (obiit, Nov. 1858), who, in his "Algebra," and also in a lengthened and celebrated article on "Analysis" in the British Association Report for 1833, has maintained that there are two distinct sciences of algebra—arithmetical algebra and symbolical algebra—but his contentions do not apply to such a consideration of abstract and concrete magnitudes as has confounded "Tyro's" reasoning powers. A person may have any degree of difficulty in understanding the meaning of differentiation of functions; but once he does understand it, he must at the same time understand the meaning of successive differentiation, since the meaning is the same in both cases. A little consideration ought to make "Tyro" perceive that whatever difficulty of reasoning can exist in a second or third differentiation the same must also exist in a first differentiation; because when we differentiate a function we may consider it as really successive differentiation with regard to the function which is the integral of the one we differentiate. He declares that though he can understand differentiating a function in the first instance, still he cannot understand differentiating its differential co-efficient, because it has been obtained as a ratio. And would he mean to assume that the function which he first differentiates may not itself be conceived as a ratio? If he tries by inquiry to warrant such an assumption, he will no doubt find greater difficulty in his way than what he seeks to have explained for him. All magnitudes can only be relative, and any analytical function would be a real abstraction if considered without reference to some supposed though arbitrary unit of measurement to serve as a common standard of proportion. Moreover, any function may be expressed as a ratio by putting it in a fractional (*i.e.*, proportional) form, with itself for the numerator and unity for the denominator. The differentiation, too, of such functions as sin. x or tan. x is the differentiation of a ratio—the ratio which these lines bear to the radius. Taking his own example, the function mx^2, we may consider the finding of the first differential coefficient $2mx$ to be successive differentiation with reference to the function $\frac{1}{3}mx^3$, which is the integral of mx^2. With regard to any difficulty in the meaning of differentiating $2mx$ from the fact that it has been obtained as a limiting ratio, that fact has nothing whatever to do with the matter, and may be left out of consideration altogether. When we proceed to differentiate it there will be no longer any necessity to consider it as a ratio. Before differentiating a function, then, it is not of any consequence in what manner we may have derived it; if it were so, it would be necessary to consider not only derivation by means of differentiation, but also by all other possible means—as $2mx$ might be derived from $4m^2x^2$ by the extraction of the square root, and there could be no more reason for any difficulty in differentiating it as a ratio than as a square root. To illustrate a second differential coefficient geometrically, let us conceive $y = f(x)$ as the equation to any plane curve; then we know that the integral of this expresses the magnitude of the area, that itself expresses the length of the ordinate, and that its differential coefficient expresses the trigonometrical tangent under the tangent to the curve, and this trigonometrical tangent gives us thus a geometrical representation of the second differential coefficient of the area of the curve. I should think, however, that the most satisfactory solution of his difficulty on successive differentiation by the theory of limits would be to compare that method with the method of derived functions of Lagrange, which excludes all ideas of ratios and infinitesimals, and therefore excludes all difficulty in the meaning of differential coefficients of any order. As Hall says, the idea of a series gives to the differential calculus "a clearness and precision of which it stands much in need." It would always be of advantage not to confine our ideas to one method only; but to understand at least the fundamental principles of two or more methods, and to make use of whichever is best adapted in each case. Lagrange's method is to be preferred for the definitions and meaning of the science, while in practical application the method of limits or of elements is much plainer to the perception. It is quite evident, too, that the differential coefficient is the same quantity in all methods. The development $f(x + h)$, according to Taylor's theorem, is of the utmost importance in its applications, and we might consider the meaning of successive differentiation by the method of limits to be merely a means of finding the successive coefficients of the powers of the increment h in that important development. We know by Taylor's theorem that each successive coefficient of the powers of h can be derived from the preceding one by a single differentiation, and therefore we could perform those differentiations by the methods of limits, considering each of them as only a first differentiation, and thus avoiding "Tyro's" difficulty in regard to this matter. In such a manner the operation involving the difficulty in question might be considered as a means to the end.—VLADIMIR.

[61575.]—**Indicator Diagram.**—In your table of quantities you omit to give the temperature of the hot well (as in your original query), and I suppose the injection in the table is gallons per minute. If this is so it disagrees with your first statement that the quantity as well as the temperature of injection remain the same. I make the feed per I.H.P 23·37, and 28lb. of water per hour respectively, and the injection water 22·6 and 22·8 times the feed respectively, or practically in the same proportion, and temperature of hot well should be about the same in both cases. As regards the increased feed, and consequently fuel per I.H.P., I think there is nothing to add to my former reply, as the expansion is high for such low-pressure steam. How do you find ratio of expansion? Is it a variable expansion valve, and the grades you give are those marked on the stem? I think the actual expansions are higher than your table shows.—T. C., Bristol.

[61581.] — **Telephone Switch.** — I have designed the above circuit arrangements, thinking that they may perhaps suit "Enswitched." Station B can communicate with either of the terminal stations, and vice versâ, while the terminal stations



can communicate, but without the invention of B's operator. R and R, at A and C, are polarised relays, closing local bell circuits at these stations with currents passing thus ———> ; but unaffected by currents passing in the opposite direction. R at B is a similar relay, having two coils wound in the same direction, but so connected up that currents which by their direction affect the relays at A and C, leave that at B unaffected, and contrarily those affecting B leave relays at A and C unaffected. A and C are furnished with reversing keys which are lettered in the diagram according to the station with which they are designed to communicate. Normally each pair rests against the top plate or bridge. The keys at B are rather different in detail, being arranged to make, when depressed, contact with the opposite poles of a battery which is divided and put to earth. Normally they, too, rest against the bridge piece, and are thereby connected when at rest. I have, for the sake of simplicity, omitted the local bell circuits, as also the usual switch actuated by the weight of the receiver; but if the insertion of these proved to be any difficulty with "Enswitched," I would prepare a diagram of the whole. It would be necessary to arrange that A B and C should give distinguishing rings when calling, that the receiving station might know who is calling, and depress the proper key in reply. Conversation over any part of the circuit would be liable to interruption by the third station breaking in, but unless the circuit were a very busy one, I do not imagine this would prove a serious difficulty.—C. P. BARTHOLOMEW.

[61577.] — **Meridian Instrument.** — Many thanks to "J. K. P." Dent has discontinued the manufacture of dipleidoscopes, and the book is out of print. I wrote there some time ago. Would "J. K. P." kindly say how the moment of transit is known from the reflected images on the mirrors; is it by contact? If "J. K. P." would allow me, I should like to drop him a line.—HERMES.

[61589.] — **Coal Economy.**—There is one assertion in the remarks of "Sugar Cane," on p. 543, which is worth further comment. He says that this matter (presumably coal economy) is of "very little interest to your readers." As a matter of fact, it is of interest to everybody, for cheap coal is a necessity of our existence as a manufacturing nation. By "cheap coal," it should be observed, is not meant low-priced coal, but that the coal-bill, when compared with any given quantity of work done, is small—much smaller than 900 tons for refining 1,800 tons of sugar. A tax on a necessity of industrial existence is barbarous, whether it takes the form of a "royalty" paid to the landholders or of a "due" paid to a town's exchequer; but that is beyond the humbug now being reiterated about "hampered industries," when those very "industries" employ steam-engines which use double the coal that need be expended, and take long lengths of steam-pipes through the air without coating them with a "non-conductor." Some of us may live to see the time when engines will give an indicated horse-power for 1lb. of coal; but whether that may be so or not, it is well known that coal is wasted nowadays to an enormous extent. "Sugar-Cane's" remarks on p. 549 are all cane and no sugar—not a word of information; and as to his assertion that my answer (?) to his inquiry (?) is exactly what he expected, I would point out to him that (on p. 529) I expressly drew attention to the fact that, in his imaginary "inquiry," there was "not even a question on a matter of fact." Perhaps he will say what he did mean by the statement (p. 508) "I do know that, in a refinery working about 400 tons weekly, it is nearly 130 horse." Such a statement is neither one thing nor the other, and would be made only by someone who "knows nothing whatever about the matter"—to quote "Sugar-Cane."—NUN. DOR.

[61604.] — **Chemical Equivalents.** — "The Alkali Makers' Pocket-Book," by Lunge and Hunter (Geo. Bell and Sons, London), would probably suit "Vulcanite." It contains a table of "Symbols, Molecular and Equivalent Weights, Percentage Composition of (158) Chemical Compounds important to the Alkali Industry."—CHROMIO.

[61634.]—**Will o' the Wisp.**—I think Will o' the Wisp is still seen in the New Forest. What is the cause of the electric sparks over the bridge at Teignmouth, Devon?—E. R. D.

[61637.]—**Dewing of Object-Glass.**—"H. A." asks about the dewing of his telescope. I have had a Romsey Observatory for about ten years. My practice is to cover the object-glass (not dew-cap) with a stout brass cap, then the dew-cap is put on over this, and its end left open. Inside the brass cap I keep a circular piece of card with cotton wool stitched upon it. I fancy this helps to absorb moisture, but I rely more on carefully covering the glass as soon as work is done, and never leaving it open without the dew-cap, even for a moment. I have very rarely found it dewed, even with constant work in indifferent weather. The dew-cap should be long. Mine is 20in. for a 4in. glass, and is not at all too long. The second point "H. A." mentions—that the ironwork and circles become covered with moisture I also find. It usually takes place when we have a low temperature or frost at night, and thaw or warm sun by day. It used to cause me a great deal of trouble, and I tried various methods to prevent it, but without success. Gradually, I found that it did but little harm, especially if I rubbed down all the brasswork now and then. I painted some bright steel parts black, such as the end beyond the counterpoise, and for the brass circles I made chamois leather covers, which I keep on them when not in use. I always wipe them with a soft leather before putting up.—M. A.

[61640.]—**Battery.**—To MR. CONRY.—For that battery your carbons should be nearly as large as your zincs, and you can reckon about one ampère for every 11sq.in. of acting carbon surface. With four carbons, say, 6in. by 9in., both sides acting, you should be able to get in practice about 30 to 35 ampères; which would require No. 10 leads for distances up to each way; but No. 8, if you have it, will be better still.—EDWARD CONRY.

[61643.]—**Boiler.**—Steam at 45lb. pressure has a temperature of 291° F.; at a pressure of 65lb. it would have a temperature of about 312° F. A jet of steam, having a temperature of 312° F., would raise a given volume of cold water to the boiling point in less time than a jet having a lower temperature. The time required by either jet will depend on the volume of water to be heated and its initial temperature. — HARRY CARTER DRAPER.

[61647.] — **American Organ.** — Would Mr. Fryer oblige by giving a sketch of the bellows for an American organ, the size he recommends in his letter on p. 550? What is meant by the reservoir board being allowed to open 7in.? I am about making an American organ, but am puzzled to know how the bellows is worked, as the air has to be drawn through, not blown, as in the harmonium. —A. C. W.

[61647.]—**American Organ.**—Perhaps it will be of some benefit to "J. S.," and also to other readers, if I give a brief description of the arrangement now of some of the cavity boards now in general use. I agree with our friend "Organon" (p. 550), as to the peculiarity of the board described by "J. S." If "J. S." wants his board arranged as he describes he will have to order it specially. A cavity board containing two full rows of reeds is usually arranged for the 8ft. row to draw towards the back of the instrument, and the other (usually 4ft.) draws out towards the front. In a 2½ row board, the half-set of reeds draws towards the front, and is usually placed immediately above the treble portion of the front 4ft. set of reeds. A 3-row cavity board is often arranged as follows:—Back row, 8ft.; two front rows, consisting of a complete row of 4ft. (bottom row); a 2½ octave treble set of 8ft., and the remainder of the row a 4ft. bass. There is in this arrangement one 8ft. and two 4ft. basses, two 8ft. trebles to form the celeste, and and also a 4ft. treble set. There is not often more than three complete rows of reeds under the control of a single row of pallets. The above remarks apply to the cavity boards of F scale. I will here explain some of the arrangements usually found in cavity boards of C scale. A 2-row, C scale, cavity board is arranged the same as one of F scale, that is, it contains a back row of 8ft. and a front row of 4ft. pitch. A 2½ row cavity board contains an extra half set of 8ft. treble reeds placed over the treble portion of the 4ft. row. A very useful arrangement of a 3-row C scale is that which contains one row 16ft., one row 8ft., and the other row 4ft. The two former rows are placed at the back, the 16ft. row being situated immediately over the 8ft. bottom row. This arrangement, with the addition of bass and treble couplers, makes a fine instrument, quite powerful enough and of sufficient variety of tone for any moderate size room. Additional solo sets can be added by fixing on to the mortise board what are called detached tube boards, which consist only of the tubes and reeds. A series of holes, according to the number and pitch of the reeds of the solo sets, are cut in the mortise board. Over these holes the detached tube boards must be firmly cemented or glued. This arrangement requires an extra set of pallets, actuated by the main pallets, and so arranged that each set of pallets open exactly at the same time. To those who wish also to have an octave of 16ft. reeds in the bass, and who do not like the trouble of fixing the ordinary sub-bass, I may here inform them that cavity boards are now to be obtained which contain a manual sub-bass so arranged on the tube board that it is under control of the same pallets as that of the other sets of reeds; but it is not quite so powerful as the ordinary sub-bass.—G. FRYER.

[61649.]—**Defective Accumulator.**—You have got all your cells short-circuited somehow, except the one that gave off gas. Take them to pieces, and instead of the felt arrangement separate them carefully with perpendicular strips of glass, which you can get or make almost for nothing, or loop, thick indiarubber bands round them, and start again, keeping current on for about an hour and a half each time before reversing, and discharge between each reversal. The alcohol does help a little.—EDWARD CONRY.

[61649.] — **Defective Accumulator.** — Felt only adds to the resistance of the cells, and had better be discarded. I presume the sheet lead is not very thick, or you could not have rolled it. The easiest way to form a Planté secondary cell is to cut sheet lead about ⅛in. thick into plates of convenient size, depending, of course, upon the purpose they are intended for. They should then be arranged in pairs in suitable vessels and charged with a diluted solution of sulphuric acid, 1 in 10 of water. A current of at least two ampères must now be put through each pair of plates from a dynamo. On the circuit being completed, gas will be evolved from the cells, and continue to be evolved the whole of the time current is being passed through. After the charge has been continued for some twenty minutes, the current should be switched off and the cells examined. It will be seen that the plates have now changed in appearance. The ones connected to the positive pole of the dynamo have become covered with a brown coating; this is peroxide of lead, and the other with a greyish colour, this is a spongy lead. The cells should now be discharged through a high resistance slowly; when discharge has taken place the cells should be reversed and connected to the dynamo in the opposite direction. What was previously the positive plate must now be connected to the negative terminal of the dynamo, and another charge passed in. Precisely the same effect is now produced upon the lead plates as before, only that their positions are changed, and the peroxidised one is now being converted into spongy lead, and vice versâ. The same process of charge and discharge must be gone through until the whole of the lead in all the plates is converted into a spongy condition. This change is the work of some time

—weeks, in fact. The charge should be continually increased by degrees at each operation. After a week from commencing formation the cells should be allowed intervals of rest, and stand with the charge in them. As formation goes on it will be manifest by the increased charge the cells will take and give out. The manufacture of secondary batteries is a costly and tedious one. When the cells are approaching completion torrents of gas will be given off as the cells become fully charged. When this is unduly prolonged the liquid begins to heat. They should never be allowed to get more than warm. It must be distinctly understood that the dynamo must have an E.M.F. at least 25 per cent. higher than the cells being formed.—C. D. R.

[61651.]—**Induction Coil.**—On p. 550 two correspondents state that if the secondary is broken no spark can be obtained at the terminals. Will not the current spark across a small internal break, causing merely a reduction of length in the outside spark at terminals? If the original querist does not possess a galvanoscope the tongue makes a very fair substitute, and has the honour of having been commonly used for the purpose by the great pioneers of electrical discovery. A friend of mine, who made a 6in. spark coil, never had a galvanometer, and says his tongue tells him as much as my whole collection of apparatus. With practice one might, perhaps, estimate the strength of a current from terminals placed near each other on the tongue as easily as a postman tests the weight of a letter by sense of touch. There is a tendency in these days to drift too much into a love of "brass and glass."—J. BROWN, Belfast.

[61652.]—**Screw-cutting.**—Exact Whitworth threads cannot be cut with single-point tools, because with a point tool the groove only is shaped. The ridge of a Whitworth thread requires to be rounded, and this can only be done with a comb screw-tool, though it need not have more than one tooth and a half. When you wrote "chaser," I assume you meant an ordinary comb tool. Messrs. Lockwood publish a little book on screw-cutting (price 1s., post-free) which tells all about Whitworth's and other threads, and from that you will see how the exact shape is obtained for making screw tools so that nut and bolt fit.—GOOLWA.

[61653.]—**Colliery Superstitions.**— Colliers are not quite so superstitious as the question would lead many to believe; but when they show any tendency in that direction it is generally to favour themseves in some fancied way or other. They are governed more by custom than anything else; but space will not allow of anything like a full description of their customs and practices to be given. Many miners think that more falls of roof take place about midnight than at any other time; but this is probably due to the workings being quieter, and falls of roof, warnings, movements of the roof, &c., being in consequence more easily noticed. I have come across even colliery managers who thought falls of roof were more liable to take place at midnight than at any other time; but they could not give anything like a satisfactory explanation. The account given, however, of miners generally gathering at the shaft-bottom at midnight to be out of danger, is an exaggeration.—G. WORLANDS.

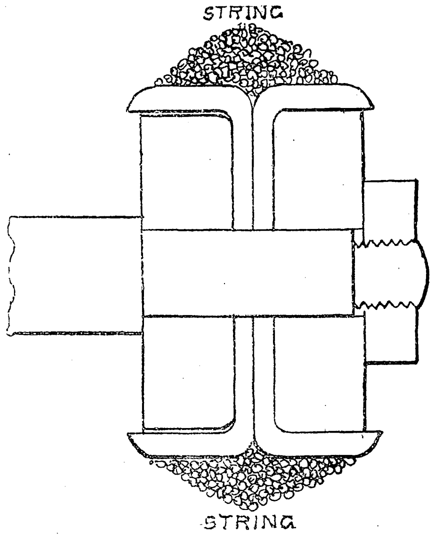
[61658.]—**Dyeing Canoe Sails.**—This querist can dye his canoe sails a golden brown by using Bismark brown. Dissolve 3oz. in 40 gallons warm water. Enter the work, and keep moving till the colour is satisfactory, then dry them, or he may dye them buff by using 2lb. nitrate of iron in 40 gallons of water. Leave them in 12 hours; get them up, pass them through a warm soda water to develop the colour. This is a fast colour.—DYER.

[61660.] — **Picking Lever Locks.** — If "J. W. R." will read "Price on Fire and Thief-Proof Depositories and Locks and Keys," published by Simpkin, Marshall, and Co., London, 1856, he will learn a good deal about the picking of locks without serving an apprenticeship to Mr. William Sykes.—D. H.

[61660.]—**Picking Lever Locks.**—I think "J. W. R." will find this rather a difficult job unless he is a good locksmith. The picks I generally use are made on the same principle as the lever key, and I have always found them successful. Of course there are several other ways; but their shapes would be rather awkward to describe on paper.—PICKLOCK.

[61664.]—**Partial Silvering.**—Hot paraffin wax would be one of the best substances, but in any case I fear you will scarcely get a clear impression with an indiarubber stamp. One of the best ways, if time and cost permitted, would be to paint the parts of the medal, &c., with fine oil, say, paraffin, and a camel-hair brush.—EDWARD CONRY.

[61662.] — **Pump for Compressing Air.** — Make piston of two thickish discs, with one edge of each rounded, the rounded sides to go back to back on the piston-rod; between them put two cup leathers back to back. These can be "cupped" thus: Provide two flanges of leather of sufficient size, soak them in cold water, put them (with the flesh



sides in contact) between the discs, screw them up tight, and then wind string round in between the leathers to force them apart till they are "coaxed" quite smooth on to the edges of the disc; leave till dry, pare edges true, and thin edges a little on flesh side. In working the skin-side at the edge will swell out and make a strong edge for working. See drawing.—T. F. S. T.

[61671.]—**To Mr. Conry, Mr. Bottone, &c.**—I cannot say absolutely, but should certainly think the uncovered wire would keep the cooler of the two. I should use a bit of good sponge for the drying agent of actual drops of liquid, or a mixture of equal parts of the calcic chloride and ordinary gypsum for moisture. If I have an ammeter to calibrate, I do it with a good tangent galvanometer, using the London "horizontal component of terrestrial magnetism" (what a mouthful!) for London and 12 miles round, or, indeed, for all the home counties if rigid accuracy be not required. For voltmeters (up to 20) I use a lot of little Daniell cells made up in egg-cups, with porous cells of blotting-paper, or for over 20 volts a dynamo whose E.M.F. at particular speeds I know.—EDWARD CONRY.

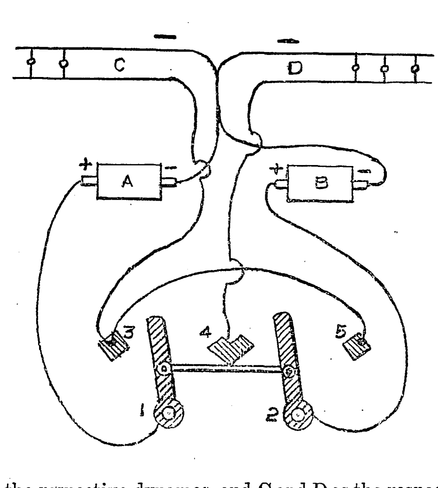
[61671.]—**To Messrs. Conry, Bottone, and "Ohm."**—Thanks for reply about drying agent. The gaslighter has improved since treated as "Ohm" described. The other two points I am not at all clear on. I have read Sprague; but can see nothing relating to matter on hand. Does a covered wire carry a larger current than an uncovered one with same heating, or why is it that an insulated conductor will carry more current than a wire uncovered and exposed to the atmosphere? What effect has insulating a wire on its carrying power? I should think that radiation would be hindered, and the safe carrying power would fall rather than rise. Also in calibrating an ammeter (having lent number containing 61131, page 352), I don't see how you know what current you have accurately. Given a mirror galvanometer of two coils, ·05w. and 2,000w. resistance, resistance-box 1—1,000w. set of secondaries, Clark cell, and variable resistance, to carry ten ampères, how could I tell when I had an ampère exactly? I tried calibration by electrolysis; but would rather do it by some quicker method. The voltmeter I would like to do separately, so that any error in calibration of the ammeter might not influence the other. What is best resistance for voltmeter for E.M.F.'s, as stated?—ATOI.

[61676.]—**Pitch Striker.**—The tool illustrated in Greenwood's book is not worth the trouble of making; but a few explanations will render its "make and action" understandable to "Young Turner." Referring to the illustration shown in Greenwood's book (p. 89, ninth edition), it appears to be drawn just half-size; but, owing to several parts being shown incorrectly, it is very difficult to understand. The section shows a bar about $\frac{3}{4}$in. by $\frac{5}{8}$in. and 8in. long. This bar has a $\frac{3}{8}$in. hole drilled lengthways about 6in. deep; the other end is pointed to drive into a handle. A steel rod is fitted into the $\frac{3}{8}$in. hole, and this rod has an arm moved by a tangent screw so that it (the rod) may be moved to a small extent in a rotary direction. The end of this rod is first drilled up, say, $\frac{1}{8}$in. diameter, and then filed off equally on both sides to make the end like a bradawl; but the hole in the centre leaves a notch. The steel rod is hardened and tempered, and the notched end which projects just beyond the end of the bar is the part used for striking the thread. If the rod is placed with its edge quite upright when the bar is flat on the T-rest, the two points formed by the notch would trace a concentric circle on a rod running between the lathe centres. By placing the edge inclined slightly from the vertical, the tool will trace a spiral, and by increasing the inclination of the tool, the pitch of the thread traced is increased. The pitch striker merely serves to mark a path for the comb chaser to follow. If this information, taken with the drawing given in Greenwood's book, does not make the "make and action" clear to the querist, I will send an illustration. The book mentioned in reply No. 61652 should be consulted by all interested in screw-cutting.—GOOLWA.

[61681.]—**Electrical Measurement.**—The ampère is the unit of current irrespective of the time for which the current lasts. The coulomb is an exact ampère per second, neither more nor less. The coulomb is very little used. The volt, ohm, ampère, and watt are the only generally used terms, except for very special purposes, such as the capacity of "condensers." The weber is merely an old-fashioned name for an ampère.—EDWARD CONRY.

[61689.]—**Heat in Dynamo.**—In my reply, p. 551, read, "When does the heat appear greatest in the coils or core?"—OHM.

[61692.]—**Electric Lighting.**—I think the following may suit you. It is a plan I have applied with success in a similar case. Taking A and B as



the respective dynamos, and C and D as the respective circuits, the wires from both circuits are united and coupled direct to the terminals of dynamo. The + terminal of dynamo A is connected to stud 1 of a two-armed switch. The + terminal of B is connected to 2. The + wire of circuit C is led to contact 3 of switch and also continued to 5. The + of circuit D is joined to contact 4. The two arms, x and z, of switch are joined by a bar K, so that when x is moved round its axis 1, z makes a corresponding movement. The switch is best made of solid brass mounts on a slate bed, with vulcanite continuity-pieces.—ARCADIAN, Failsworth.

[61700.]—**Nickel Crucibles.**—These can be bought at the laboratory furnishers for about 2s. each. They will stand fusion of silica or alkaline substances. Acids dissolve the metal. On ignition the crucibles lose weight much more rapidly than platinum does. See results of experiments by Wanklyn and other chemists in *Chemical News* for past few weeks.—CHROMIO.

[61702.]—**Turning.**—Fix the ram in the dog-chuck, and let it run in the revolving stay or thimble, and proceed.—WALLACE NEWLAND.

[61702.]—**Turning.**—What is the difficulty? You can chuck it between centres, and then surface the end to within a $\frac{1}{4}$in., which can afterwards be cleaned off with a file.—T. C., Bristol.

[61703.]—**Saw.**—Make a piece of flat iron red hot, and hold the saw on it with the teeth pointing to the sky, and cool, when the colour is a deep purplish brown.—T. C., Bristol.

[61704.]— **Cocaine.**— Probably the spray or blowing of cocaine would be preferable to injection for small teeth and stopping operations. The strength of solutions as applied to mucous membranes varies from four to ten per cent. Take care that you don't let the cocaine fall into the larynx, as Dr. Havilland Hall has recorded a case (*Lancet*, Nov. 21, 1885), where it produced severe laryngeal spasm.—B.SC., Plymouth.

[61704.]—**Cocaine.**—If "C. E. A." is a dentist in practice he must have let himself fall very much behind so as to put such a query. For hypodermic injection to produce local anæsthesia in extractions one grain is generally sufficient for one operation,

the time of taking effect, being longer or shorter according to the patient, usually from four to fifteen minutes; for an operation extending to three or four extractions $2\frac{1}{2}$ grains may be used. As regards its use in stopping teeth, a practical demonstration by a brother dentist would be of more real value than any directions, as the circumstances vary, and the treatment of one case would not do for another. The strength is still a matter of opinion, as some dentists use it full strength, and others more or less diluted. If "C. E. A." is not a competent dentist, or registered, then he will, if wise, defer experimenting on the human subject, unless he wishes for "free board and lodgings."—DENS.

[61705.]—**Faulty Micro. Prism.**—Micro. objectives require to be specially adapted for binocular work; any ordinary objective cannot be used with the binocular prism. You are using too high powers; but it can be done by a very careful manipulation of the mirror with the $\frac{1}{2}$in. Your prism, I have no doubt, is quite as good as you can make it; leave it alone, and practise with the mirror.—T. M.

[61707.]—**Centre of Pressure.**—If you can manage the calculus, "Besant's Hydro-Mechanics" will suit you; but I may at once say nothing so advanced as this is required for the advanced stage examinations, but for honours. Firstly, the centre of pressure in any plane surface in a fluid, and not horizontal, is always below its centre of gravity. Besant gives a case of a quadrant of a circle with its edge level with surface of water, and the depth of centre of pressure below surface is $\frac{3}{16}\pi r = {\cdot}59\, r$ where r is radius of circle. The centre of pressure of a semicircle will evidently be at same depth. The c.g. would be ·424 r below surface; you will therefore see by this that centre of pressure is below c.g.—T. C., Bristol.

[61707.]—**Centre of Pressure.**—It is impossible to give a formula suitable to all cases. For a semicircle we shall have to use the integral calculus. Suppose the origin at the centre, axis of x horizontal, that of y vertical, downward measurements (for depth) positive, a the radius. Now, suppose we take a horizontal strip of the surface at a depth y and of a width dy, which is supposed infinitesimal, then the area of this strip will be $2\sqrt{a^2 - y^2}\,.\,dy$, and the pressure on the strip will be that area multiplied by the depth, and by a constant P, whose value depends on the nature of the liquid and the unit of measurement; the pressure on the strip will therefore be $2\,\mathrm{P}y\sqrt{a^2-y^2}\,.\,dy$. Again, the moment of this strip round the axis of x will be the pressure on the strip multiplied by its distance from the axis of x—that is, it is to be multiplied by y, and the sum of the moments of all the strips which make up the semicircle will be—

$$2\,\mathrm{P}\int_o^a y^2\sqrt{a^2 - y^2}\,.\,dy.$$

If this is worked out, it will be found to come to $\frac{\mathrm{P}\,a^4\,\pi}{8}$. Now, the sum of the moments divided by the total pressure of fluid will give the length of the arm or distance from axis of x at which the resultant pressure is applied—that is, the centre of pressure. The total pressure is the area of the semicircle multiplied by the depth of its centre of gravity and by the constant P; the depth of the c.g. in a semicircle is $\frac{4\,a}{3\,\pi}$, and the area is $\frac{\pi a^2}{2}$ which gives a total pressure of $\frac{2\,\mathrm{P}\,a^3}{3}$. Divide the result obtained for moments by this, and we get depth of centre of pressure below surface $= \frac{3}{16}\,a\,\pi$. —M.I.C.E., Bath.

[61709.]—**Medical Electricity.**—You must get an induction coil. The resistance of the human body is too high for even 20 cells to be of any use without one; but with the coil, one cell will do.—EDWARD CONRY.

[61712.]—**Chloride of Silver Battery.**—Skrivanoff's cell is an ordinary chloride of silver excited by a solution of caustic potash. The method of construction has been given several times. Chloride of silver is fused in a porcelain dish, and poured into a mould of any convenient shape; a cylindrical one is best. Previous to pouring, a silver wire should be placed in the mould and chloride run round it. This serves for the positive pole. Two indiarubber rings should now be slipped over the round stick, and a cylinder of zinc fitted outside them. The elements must then be placed in a suitable vessel and charged with a solution of caustic potash. Very little current will be generated at first, owing to the resistance of the chloride. After the cell has been at work some little time the current rises to its normal strength. If you require the full current at once, the cell should be short-circuited until sufficient current is obtained. Chloride of silver cells are not used for house-lighting: the first cost is too great.—C. D. R.

[61714.]—**Steam Ports.**—Drill two $\frac{1}{8}$in. holes up for ports. Yes, cast brass will do for dome—turned in lathe to, say, $\frac{1}{8}$in. thick; but why have a dome at all?—T. C., Bristol.

[61716.]—**Electric Light from Batteries.**—See replies to 61452.—OHM.

[61716.]—**Electric Light.**—Batteries do not maintain light efficiently. Even if they did, the term 10c.p. is so vague that it may mean anything. You must state what the resistance of the lamps is, and also the current required. There are plenty of batteries in the market, but all fail on the score of efficiency.—C. D. R.

[61720.]—**Photo Exposures.**—The table you want is to be found in Platt's "Exposure Book" (Cartwright and Rattray, Manchester, 1s.), and is to the following effect for the example you give: Sunshine, 1; diffused light, 2; dull, 3; very dull, 4; gloomy, 5. I shall be glad to give you any help (being a fellow townsman) on your writing to 23, Hyde Park-road.—B.SC., Plymouth.

[61721.]—**Quick Writing of Notes.**—If "J. R." will get the *Journal of Science, Letters, and Art*, Vol. V., No. 1, price 6d., from Wm. Reeves, 185, Fleet-street, he will find therein a paper, by the Rev. W. J. B. Richards, D.D., on a method of using abbreviations or symbols to facilitate quick writing. Dr. Richards uses the letters of the alphabet, either singly or in combination, to represent words in common use, and the accentuation shows the parts of speech. It seems both an easy and a good method.—SM.

[61721.]—**Quick Writing of Notes.**—Many of these systems of shorthand turn out to be inconveniently longhand when put into practice. An easy way of taking short notes quickly is to ignore vowels and spell words as they are sounded. For instance, to explain what I mean, I will quote the first part of "J. R.'s" query written in the form I suggest: Sm tm snc, bt do nt knw wn, sw advt. in r's stm abrvtd lnghnd." It will be observed some vowels must be used to assist in translation, and even then some practice must be given to this style of writing, which, in my humble opinion, would be more profitably utilised by devoting one's time at once to Pitman's system of shorthand. Get a 6d. primer of this art, and I think you will see I am right.—S. BRETTON.

[61721.]—**Quick Writing of Notes.**—If "J. R." watches the advertisement columns of the London dailies he will very likely come across a notice of one of the abbreviated longhand systems: if I am not mistaken, a new one appeared the other day under the title "Swift-hand." I examined an abbreviated longhand system some years ago, and found it to consist mainly of contractions for oft-recurring words and a general omission of vowels. I don't know whether "J. R." requires information for reporting or cognate purposes; but if he does, I can inform him from my own experience (though now a shorthand writer), that reports, and very full ones, too, can be taken by one well conversant with abbreviated longhand and a rapid pen (or pencil) man. There is no greater mistake than to suppose that a good shorthand writer will necessarily make a good reporter; and conversely, an intelligent man, clever at abbreviated longhand, will take a better report than a mere stenographist without the other reporting qualifications. "J. R." will save some time if he learns thoroughly the various contractions, such as—/, the; o, of; t, that; w, with; f, for; fm, from; wh, which; wd, would; cd, could; h, have. This list (from Reed's "Reporter's Guide") can be amplified to an almost unlimited extent. By committing one contraction after another carefully to memory, by-and-by a large stock of abbreviations will be easily and pleasantly at the service of the writer. But however expert he may be in abbreviated longhand, a good memory is an indispensable adjunct to its use.—ARTHUR MEE.

[61721.]—**Quick Writing of Notes.**—A system of abbreviated longhand, by Ritchie, was extensively advertised some years ago, but it appears to have dropped out. I obtained a copy at the time, and found that the work possessed no particular merit, and was not very brief. It gave a few special contractions for very common words, and directed that only the consonants should be written in the majority of words. There is a recent system by Anderson which is very ingenious and rather elaborate. It is undoubtedly brief, but I should say there is a lot to remember, and that it would not be applicable to unfamiliar words. If you care to communicate with me I will send you further particulars of the last-named scheme and the author's address. I am afraid that unless you use a very large number of contractions you will find abbreviating longhand disappointing as regards speed, and I have found from experience that if written roughly, as is usually the case in note-taking, it is at least as difficult to read as roughly-written shorthand, if not more so. Have you tried shorthand and failed, or are you afraid to tackle it? A system I use might suit you. It is by far the best for scientific and literary purposes, as its great characteristics are legibility and freedom from ambiguity. I do not speak as a mere partisan, knowing one system only, but as one who has given much time and attention to the examination of various systems, old and new. I will not mention the author's name here, as it might provoke a shorthand discussion, which would hardly be suitable for the columns of the "E. M."; but I shall be happy to tell you more about the system and assist you by letter, gratis, if you like to attempt to learn it. It can be learned in a week, and there is little to remember. It can be scribbled at a high rate of speed without becoming illegible, and shows all the leading vowels written in with the consonants in proper order. It does not require delicate penmanship, and can be written at a useful rate with little practice.—F., 5, Hawstead Villas, Catford, London, S.E.

[61722.]—**Photography.**—It is quite possible to get an "Optimus" lens which will give the sharp definition referred to by "A Novice"; but if he has to buy it without a trial and can afford the price, he is safer to get a Ross R.S. or Dallmeyer R.R.—B.SC., Plymouth.

[61724.]—**Telephonic.**—Blake's transmitter is generally acknowledged to be the best. The patent covers such a wide area that it embraces nearly all forms of carbon transmitters. I suppose you are aware that they cannot be purchased?—C. D. R.

[61724.]—**Telephonic.**—Querist asks which is best form of transmitter? On this point there will be difference of opinion. He should try the Blake and the Gower-Bell. Both (I might say all) have been illustrated in your columns.—NUN. DOR.

[61724.]—**Telephonic.**—I think it is generally conceded that the "Blake" transmitter is the best all-round form to be used in connection with telephone, but I would warn "Zirconium" that its use is most carefully protected by patents. Its principle is very simple: A carbon button has pressing against it a platinum point, the amount of pressure being regulated at will by means of a little screw pressing against a spring carrying the said button. —S. BRETTON.

[61724.]—**Transmitter.**—A very good and cheap transmitter can be made with some pieces of arc-light carbon, after the style of the Gower-Bell transmitter, which is one of the best. If you intend making one, I shall be happy to give details of mine, which are copies of an amateur's private line set. Of course, the Blake transmitter tops the list; but there are many others very efficient, especially for short lines.—IOTA.

[61725.]—**Photographic Query.**—You don't give enough particulars; you must give ratio of aperture to stop, date and hour of exposure, if sunshine, diffused light, dull, or very dull. It looks like, though, that you have over-exposed. Try four seconds and develop with a sodic sulphite developer.—B.SC., Plymouth.

[61725.]—**Photographic Query.**—"Four stop" does not convey to one's brain the least idea of its value, and especially not knowing the rapidity, &c., of the lens. Your negatives, however, are sure to be over-exposed: they are very quick plates; 8 secs. is much too long. Try less exposure, also develop longer, with more bromide in the developer; it may be due to under-development.—R. A. R. BENNETT.

[61726.]—**Cotton-Seed Oil.**—The addition of cotton-seed oil to olive oil would undoubtedly be a fraud—as a matter of fact, it is one frequently committed—because olive oil is so much more expensive. If the querist likes cotton-seed oil, there is no reason why he should not use it. Perhaps he will say what he means by its "recognition" as a food. Surely no one wants to adulterate it.—NUN. DOR.

[61727.]—**Locos—L. and S.W., G.E., L.B. and S.C., L. and S.W.**—"Dane" was No. 147, a four-coupled engine, recently employed in goods traffic on the main line. "Castleman" was, I believe, No. 159, of the same class as 157 "Clyde," cyl. 17 by 22, coupled wheels 7ft. This class had Beattie's patent coal-burning firebox, and was built about 1859. Most of the engines are now scrapped. 470 is a four-coupled bogie express, class 470-478, drivers 6ft. 7in., weight in working order $46\frac{1}{2}$ tons. Built by Robert Stephenson and Co., 1884. Full dimensions given in "E. M.," Vol. XLI. p. 35. The 135-146, 147, and 460-469 classes have the same dimensions. 521 is a bogie tank, built by Dübs and Co., 1885, of the same class as 517 to 525, 415 to 432, 45, 47 to 57, 169-171, 173, 479 to 495. G.E.: 659 is a four-coupled radial tank, built at Stratford, 1885. Class 650-659. Weight loaded, 51 tons $18\frac{1}{4}$cwt. Full dimensions were given in *Engineering*, Vol. LIX. p. 204. I have seen two other engines of this type, Nos. 673 and 676; but do not know how many similar engines there are at work. L.B. and S.C.: 34 "Balham," Brighton, 1876, and 252 "Buckhurst," Neilson and Co., 1881, both belong to the numerous class of passenger tanks designed by Mr. Stroudley in 1876, and fully

described in *Engineering*, Vol. XXI. p. 28. Weight empty, 34 tons 7cwt. 68 "Clapham" belongs to the "Terrier" class. Its date is 1874, Brighton Works. I believe that all the engines between Nos. 35 and 83 belong to this class, and that it is described in *Engineering*, Vol. XXXII.—V. J. B.

[61728.]—**Motor for Small Organ.**—In hydraulic blowers of the ordinary reciprocating type the rod does not work the main slide-valve (an arrangement that must come to a stand), but works the slide-valve or four-way of a subsidiary cylinder, which in its turn moves the main slide-valve. The main slide-valve is usually made to form its own piston. It is possible to arrange a spring action; but it would be jerky and noisy, two defects already difficult of remedy in engines of this class. I will send "Pressure" a sketch if he will send me his address.—T. CASSON, Denbigh.

[61730.]—**Conservation of Energy.**—Total heat of perfect combustion of 1lb. coal is equal to 14,500lb. of water raised one degree Fahr. or $14,500 \times 772 = 11,194,000$lb. raised one foot high. A first-class engine uses, say, 2lb. of coal per I.H.P. per hour = 22,388,000 foot-pound units, and does $33,000 \times 60 = 1,980,000$ foot-pounds of work = $1,980,000 \div 22,388,000 = \cdot 09$, or, say, $\frac{1}{11}$ the theoretical energy of the fuel. Part of the heat goes up the chimney, however.—T. C., Bristol.

[61732.]—**Models of Buildings.**—If I wanted to do this myself, I should try a mixture of French chalk and gold size, which would set quite hard, but would stay soft long enough to be marked if mixed to the right consistency. Portland cement might also do. Either could be coloured so as to imitate old stone.—R. A. R. BENNETT.

[61735.]—**Screw-Cutting.**—Having first centred and drilled the steel, get a tool the same shape as you want your buttress-thread to be, tighten in rest, and put running stay on the saddle to prevent it from springing, and proceed. Respecting what number of wheels you will require, to cut your thread: you do not state number of threads to leading screw; but assuming it to be 2, then $\frac{3}{4}$in. pitch = $1\frac{1}{3}$ thread in 1in.; $\frac{2}{1\frac{1}{3}} \times 30$ (to obtain wheels with even number of teeth); $\frac{60}{40}$ = 60 for mandrel, and 40 for leading screw, and any wheel that will gear for intermediate. As regards the round thread: the leading screw, the same as in the last question, put on the same wheels; but cut the thread as a square-threaded screw, and then put radius tools in for rounding off the tops. Grind your screwing tool slightly smaller than thread wants to be for roughing cut.—WALLACE NEWLAND.

[61737.]—**Size of Steam Boilers.**—You are asking a strange thing. The engine would want a different size boiler according to the pressure at which it was worked, the speed it was run, and the grade of expansion, all of which would have to be considered in putting in a suitable boiler.—T. C., Bristol.

[61739.]—**Sand Figures.**—First see that the plate (which should be perfectly square or round, and the edges well ground) is firmly fixed. It is a good plan to support it underneath at the centre by a fine-grained cork, with a thin disc of the same above on which the point of the clamp-screw may rest. A firm elastic support is thus obtained, without any fear of the plate being unduly strained or flying to bits when the screw is tightened up. Next see that the sand used is quite dry, free from bits, and fine enough. The surface of the plate should be quite dry, or the sand will adhere to it and be sluggish in its motions. The violin-bow should be well rosined before commencing, and the strokes should be made with a firm hand, the same pressure being maintained throughout. Practice alone will give you full command over the bow. It will be as well if the fingers of the left hand be damp, but not actually moist. Finally, it is of the utmost importance that all draughts be excluded. Having got everything in working order, we will consider the different ways in which the method can be varied. (1) The point of support of the plate. The greatest variety can be obtained from a plate fixed at the centre; but many very beautiful forms may be obtained when fixed at some eccentric point, provided it be *symmetrical.* By this I mean some point situated either on a diagonal, at a distance from the corner which is an aliquot part of the diagonal, or on a diameter at a distance from the side which is an aliquot part of the diameter. For instance, many interesting figures are got with a plate fixed at a point on the diagonal, one-fourth of the diagonal distant from the corner of the plate. (2) The point of application of the bow. This may be either at a corner, or the centre or other aliquot portion of the side. (3) The position of the nodal points. These may be at the edge, or some symmetrical point on the upper surface of the plate. Then, again, there may be only one nodal point, or there may be several; further, one nodal point may be at the edge, and another on the plate. In short, by varying the position of the three above points an endless number of different figures can be easily obtained. It is as well to go to work systematically, and not go skipping about from one to another, building up the figures as it were, by varying the position of the nodal points, and passing from the simple to the more complex forms. Thus, if a plate be fixed at the centre, and the bow be applied at the middle of the side, the sand arranges itself along the diagonals. If now the fingers be applied at equal distances on either side of the bow, the previous figure will be produced, with the addition of four semicircular arcs, and so on. I hope to hear that "S. Z." has been able to produce the 300 figures, and many more besides.—REYMOND.

[61740.]—"**Frankenstein.**"—It is now published as a sixpenny book, and may be seen at several of the shops in Holywell-street and elsewhere.—SIGMA.

[61740.]—"**Frankenstein.**"—This can be obtained in a cheap form from Messrs. Dick, publishers. I think their address is 313, Strand. It is to my mind a horrible work.—S. BRETTON.

[61740.]—"**Frankenstein,**" by Mrs. Shelley, has recently been republished by Messrs. Routledge and Sons in their "World Library." This is a series of cheap reprints of English classics; the price is threepence per volume in paper covers.—W. J. S.

[61740.]—"**Frankenstein.**"—This work is contained in one of the half-yearly volumes of the "Illustrated English Library," published by John Dicks, 313, Strand, London. As many of the novels are published separately, "Frankenstein" may be so had; but full information will be given on application at the above address.—DENS.

[61740.]—"**Frankenstein.**"—A cheap edition of Mrs. Shelley's "Frankenstein" is published by Routledge at 6d. I don't think it was written for a "wager," but there was something of that about its origin. Byron, Shelley, Mrs. Shelley, and Polidori each agreed to write a ghost story, and Mrs. Shelley was the only one who kept to the agreement; but she did not write "Frankenstein" in a few hours. I have mentioned the edition I know: doubtless there are others.—NUN. DOR.

[61741.]—**Brake Trial at Ipswich.**—This trial was made on the Hadleigh and Bentley branch with a Great Eastern engine, No. 20, and six coal waggons fitted up with the Parker-Smith brake; it is put on by a dead weight falling down, and held off by air or vacuum holding the weight up. It is illustrated in *Engineer* and *Engineering*, but it does not seem a brake likely to come into large use—the leakage round each piston and the want of power at high speed seem fatal objections.—LOCO.

[61745.]—"**Mechanics.**"—Buy up the last dozen numbers or so, and you will find all you require—the last half dozen I think has sketch. Simply a ratchet wheel and pawl connected to lever and moved by table.—T. C., Bristol.

[61746.]—"**The Last Quarrel.**"—What "Arques" wants is entitled "The First Quarrel"—Tennyson; p. 625 in my 1883 copy.—H. T. W.

[61748.]—**Electric Light.**—You could light four 20's, but it will depend upon the efficiency of the dynamo. Small machines have been described several times; you had better look up back numbers.—C. D. R.

[61748.]—**Electric Light.**—Certainly you can; and if you will say the maximum actual H.P. your engine will give, or about that, I will send you dimensions, &c., for a dynamo. The relations of nominal and actual H.P. alter much with different varieties of gas-engine, and I do not know how it stands with the "Bischopp."—EDWARD CONRY.

[61748.]—**Electric Light.**—A small dynamo to work off your gas-engine would not light much more than four 10c.p. lamps (actual); but that would be, most likely, quite as good as gas. Crofts, of Dover, supplies castings that might suit you. No. 14 Cu mains and 18 branches would be necessary. The dynamo would be about 70 per cent. efficiency, and then your leads would take a watt or two. Is the power given indicated—i.e., actual, or the nominal H.P. of the engine?—IOTA.

[61748.]—**Electric Light.**—"Selim," being a cutler, has a good reason for using the electric light; but his two-man engine will not do much, as I suppose at the utmost it will not give more than half a horse-power, if so much. Probably he wants the engine during the daytime for other work, or he might employ it in charging secondary cells, which, however, would make the light very expensive. To light a shop in such a manner as to make it worth while, he will find that an engine of at least one horse-power is requisite.—NUN. DOR.

[61748.]—**Electric Light.**—Your better plan will be to utilise your 2-man gas-engine to drive a small shunt dynamo, but specially wound to suit requirements, so as to charge during the day four small 60-ampère-hour (Woodward's spongy lead storage batteries). These plates have ample surface, and would feed six of our 8-volt 5c.p. low resistance battery lamps for general requirements; and during the evening, if you wanted additional light, you could run the engine and dynamo direct to feed another circuit of lamps installed of suitable voltage. By the above combination you could obtain fair and satisfactory results from the small power at command, and for an expenditure of, say, about £15; but if you do not mind a little extra outlay, by all means change your engine for one of 4 or 5-man power, from which you could obtain much better results, as you would be able to charge eight cells, and use our 15-volt 12c.p. standard lamps, which, when fully incandesced, would absorb 2 ampères to obtain full candle-power; and if you wind your machine to give 34 volts you can run three lamps for direct lighting coupled two in series as one lamp, and thus obtain better results from a given expenditure of energy. If you reside in or near London, and desire to inspect such an installation as the latter, you can do so; or if you insert your address, we will communicate direct upon the subject. But for the present let us advise you, if you mean to introduce electric lighting, do it well, or not at all. See our advertisement in the Sale Column for small sets of plant.—SHIPPEY BROTHERS.

[61750.]—**The Exact Time.**—Nothing can be easier than some simple form of transit instrument. It need not be expensive; if within half a minute is near enough for you.—S. BRETTON.

[61750.]—**The Exact Time.**—Why does not "Montmartre" establish a small transit instrument, and thus obtain "the exact time" by original observation? There is a form specially adapted to a window frame, where no better position can be had, though its strict adjustment is evidently more difficult. Admiral Smyth, in the Bedford Catalogue (Prolegomena), tells his readers how Mr. Troughton was able to use a transit even in Fleet-street, taking the instant of passage when a star vibrated (thanks to passing vehicles) equally on each side of a wire, and how he jocularly insisted that such conditions were preferable to perfect steadiness.—ANTARES.

[61751.]—**The Exact Time.**—Do not all signal-boxes and railway signals receive a time signal once a day? The Midland, I believe, get it at 10 a.m. Surely there can be no difficulty about the matter, as nearly all railways accept Greenwich mean.—C. D. R.

[61751.]—**Exact Measures.**—To begin with, tape measures in any form are not considered accurate. A really reliable standard for any amateur is a machine-divided engineers' steel flat foot-rule, procurable at most mathematical instrument makers for a shilling or eighteenpence. Mine is marked "Chesterman, Sheffield." London makers use the standards in Guildhall.—S. BRETTON.

[61752.]—**Dirty Ceiling.**—Make up some coloured distemper for the mouldings and centre rose, and paper the remainder of ceiling with one of the many excellent designs now produced for this purpose.—S. BRETTON.

[61757.]—**Legal**—"**Back Letters.**"—Your "back letter" is of no use; you actually got cash for the amount in the bill, and even in the hands of your brother it would be good against you. A "B. L." is given and is of limited benefit under the following circumstances:—Supposing you had granted the bill referred to for your brother's accommodation, and had received no value for it, and he gave you a "B.L." narrating these circumstances, you could produce this letter if he (the drawer) took proceedings or diligence on it. If the bill, however, got into the hands of a third party you would have to pay it, but would be entitled to relief from your brother. What you have to do is to get back the bill from him and give up his letter: otherwise he can come down on you at any time.—B.SC., Plymouth.

[61759.]—**Oxygen Gas (Liquefaction of).**—This gas cannot be liquefied by any pressure at ordinary temperatures. There is for each gas a certain temperature, above which it remains unchanged in appearance at any known pressure, but below which a certain pressure will cause a part or all of it to become liquid. This was called by our famous townsman the late Dr. Andrews its "critical temperature." Although the simple apparatus with which Andrews carried out his beautiful and accurate research was not capable of liquefying what were then called the permanent gases, he considered that the critical temperature of oxygen was probably below 110° C. In 1877 the liquefaction of oxygen was accomplished by Cailletet, of Paris, and about the same time, in a more perfect way, by Pictet, at Geneva, using a powerful apparatus, in which the gas, inclosed in a long glass tube, was subjected to a pressure of 320 atmospheres and a temperature of 140° C. An account of the apparatus appeared in these pages soon afterwards.—J. BROWN, Belfast.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list, and if still unanswered are repeated four weeks afterwards. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "G. J." has replied to 61059, 61250; "Bertram Blount," 61124; "East Anglian," 61347.

QUERIES.

[61763.]—**Bellows.**—I have a pair of pear-shaped bellows, which has a few small holes in. I want to repair the same, but I cannot get my hand in the trap underneath to do blind stabbing. Which is the best and most perfect way of repairing the same?—A SUBSCRIBER.

[61764.] — **Hydraulic Bending.** — Will any of "ours" kindly give formula of hydraulic pressure required for bending cold steel plates? For example, say Siemens steel plate, ⅜in. thick, 2ft. 6in. wide, to be bent to a right angle, with inside radius of curve 2½in.—H. S. P.

[61765.]—**Staining or Dyeing India Matting.**—I want the best and easiest means of dyeing, staining, or colour-varnishing pieces of India matting about a yard square. Colours preferred—Navy blue, dark green, or crimson.—ZERO.

[61766] — **Coal and Water.** — If 1lb. of coal evaporates 10lb. of water at the atmospheric pressure, or 212° Fahr., how much water will 1lb. of coal evaporate at 80lb., 90lb., and 100lb. pressure, everything under the same circumstances, with exception of pressure?—DUTCH PAUL.

[61767.]— **Gun-Barrel Boring.** — Will someone oblige me by giving a description of the tools used in boring gun barrels? A sketch of the drills, &c., will be the best. I do not wish to bore gun-barrels myself; but often have lengths of pipe to bore, and can get nothing like so good a hole as there is in the commonest gun-barrel.—S. B.

[61768.]—**Battery for Lamp.**—Kindly inform me how many cells (using chromic acid) would be requisite to light a 5-candle lamp, as advertised, say, by Shippey Bros., and could you give me any hints as to fitting up battery?—SEVERGA.

[61769.]—**Oxide of Copper Battery.**—Will someone inform me what is the proper proportion of copper oxide to caustic potash, and what is the electro-chemical combination and equation?—RIFLE.

[61770.]—**Electric Motor for Sewing Machine.**—Will Mr. Bottone, or others, give me particulars and sketch of how motor is connected to sewing machine to drive it? Also connections from battery to motor?—ELECTRO-MOTOR.

[61771.]—**Photo. Developers.**—"Burton" recommends sulphurous acid in the pyro. solution. What is this, as I cannot find it in chemical lists? Is it same as sulphuric, or what? How long will a pyro. solution with this added, as, I suppose, a preservative, keep good? Fry gives citric acid. Which is best?—J. R.

[61772.]—**Lantern Transparencies.**—Let N be a whole-plate negative, L be a lens, P a positive chloride plate 3¼ square; N, L, and P being arrranged in a line thus—

N..............................L.....................................P

L being a view lens of either 11in. or 4½in. focus, with, in either case, ¼in. stop. Will someone tell me how to calculate roughly the distances of N L and P L, so as to enable me to construct a copying camera in which to reduce whole plates to 3¼ square, and also say probable exposures?—J. R.

[61773.]—**Compressed Oxygen.** — I should feel greatly obliged for any information respecting the compressing of oxygen gas for limelight, likewise the simplest way to make the wrought-iron bottles, what pressure generally obtained, &c.—G. G.

[61774.]—**Bronzing Iron.**—I have a small quantity of malleable bright iron tips in stock. Can you kindly inform me how I can make them appear as brass or copper on the face? I have been told copperas, and tried same without effect. I am now having the rest bronzed over at the casters; but what I have in stock will not sell a long-side of these. Is there any lacquer I can use?—C. KEMP.

[61775.]—**Legal.**—A. is the occupier and owner of a semi-detached house. B., the owner of the other house, lets it to C. on a lease for seven years. After about three years, C. allows the drains to get stopped, and, also, a water tap constantly leaking causes an overflow to A.'s house, which is on a slightly lower level. Great signs of wet showing themselves, and being ignorant of the cause, A. has a large hole dug in front of the kitchen range, into which gallons of impure water flow, and are traced to the foundation wall between the two houses. The inspector of nuisances forces his way into B.'s house and pronounces the drains choked, which explains the cause of the water. C. (the tenant) is obliged by a magistrate's summons to unstop them, but immediately his goods are sold by auction. B. takes possession, and sells the house at once. A. has bills sent in amounting to £4 15s. 10d. for work done in the kitchen, beside months elapsing when it could not be used. B. refuses to pay it, C. has left, and is there any remedy for A., who is in a hard case?—A. B. C.

[61776.]—**Water Question.**—In order to induce condemned criminals to confess the names of their accomplices, it is stated to have been customary in the reign of Louis XIV. in France to pour down their throats through a horn as much as twelve quarts of water. I do not understand how this was possible. Would not the water when it became oppressive to the stomach naturally be thrown up, and, if so, how could, or was this prevented? Any information on the subject of this torture would be acceptable to—RETLAW.

[61777.] — **Ferro-Chrome.** — Will someone kindly give the method of determining chemically the amount of chromium in the above when manganese is also present?—GAMES.

[61778.]—**Blake Transmitter.**—Could some correspondent kindly inform me where I can obtain a sketch of the connections of the Blake transmitter, as used by the National Telephone Co.?—TELEPHONIST.

[61779.]—**Micro. Mounting.**—Can Spirillum undula be mounted as a permanent specimen to show the flagellum as well (or better) than when it is living? If so, will some of "ours" say by what means? Have tried a great number of stains and mounting in various ways, but with only poor success.—MOYHITT.

[61780.]—**Mainspring Gauge.** — Would someone tell me the use of the different size circles on watch mainspring gauge, numbering 1 to 16? One gauge has only circular marks, and the other has them all sunk with hole through centre.—TINKER.

[61781.]—**Family Oven.**—Can any reader inform me what materials I should require for building a fair-sized baking oven? Also the best shape for the same?—CONSTANT READER.

[61782.]—**Sugar.**—Will some correspondent inform me how to purify this? I have Dutch crushed and Russian granulated, and wish to make a clear, bright solution, removing all impurities from the same. Also would like to know how to tell the variety of sweetness in the different sugars. I do not think the saccharometer gives this, although it may give the density; but do these agree—density and sweetness? A little book on sugar I would like. Can anyone suggest one?—J. GREEN, March.

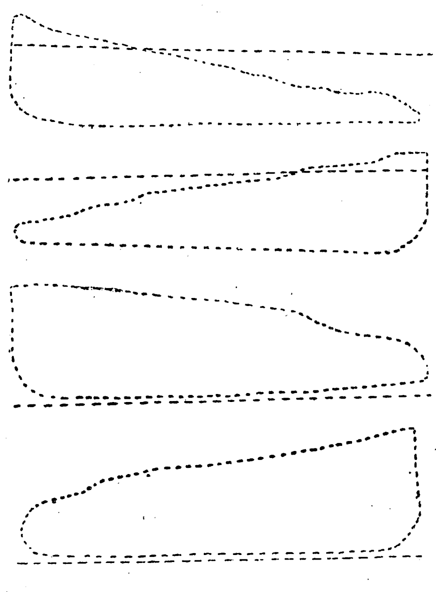
[61783.]—**Flywheel for Gas-Engine.** — Would some of our readers kindly inform me what size and weight of flywheel will suit a non-compression gas-engine with cylinder 4⅝ dia. and 10in. stroke?—REVOLUTION.

[61784.] — **Phonograph.** — I have just bought a phonograph, second-hand. It is perfect, and has a receiving mouthpiece at one side and speaking mouthpiece at the other. I would be greatly obliged for instructions how to adjust and work successfully.—A REAL IRISHMAN.

[61785.]—**Corn Store.**—I propose to build a small corn store with ground floor and loft 75ft. long by 35ft. wide. The loft will hold about 300 tons of oats. I propose to make the walls and roof of corrugated iron, lining the walls inside with 1in. or ⅞in. boards, leaving a space of 4in. between boards, and outside walls of corrugated iron of about 4in. This space to be filled with concrete. Loft proposed to be of deals 9in. by 3in., on beams, laid across, and, say, 10ft. apart, and two props to each beam. Would be greatly obliged for hints and opinions as to whether this would be a good and successful job or not.—A REAL IRISHMAN.

[61786.]—**Organ at Albert Hall.**—Can anyone inform me if the organ in the Royal Albert Hall, Kensington, London, is worked by steam power, and how many horse-power is employed for the working of it?—A TWENTY YEARS' SUBSCRIBER.

[61787.]—**Indicator Diagrams.**—The accompanying diagrams are taken from a compound horizontal tandem engine: cylinders, h.p. 18in., l.p. 36in.; stroke,



5ft.; revs. 45 per min.; boiler pressure, 60lb. Will any correspondent tell me if there is any rule to calculate the evaporation of water from the diagrams, and, if so, will he please apply it to the inclosed diagrams?—J. C. T.

[61788.]—**Anchor Ice.**—Will someone who knows tell us whether ice does form at the bottom of streams, and, if so, state what enables it to do so?—DOUBTFUL.

[61789.]—**Loss of Power in Gas-Engine.**—Will some able correspondent kindly answer? Is there not a great loss of power by employing so heavy a flywheel? I do not want it explained that it is necessary to the steady running of the engine. As a practical mechanic, I understand that; but what would be the gain if it could be dispensed with? The reason of my query is I have an invention that would take up the sudden impulse of the piston and give it out again during the rest of the stroke, instead of as now. I think there must be a great loss of power in the sudden impulse attempted to be given to the flywheel. Please give plain figures, as I do not understand algebra.—T. N. C.

[61790.]—**Acid-proof Gilding.**—Will brass, if gold gilt, stand nitric acid for a few minutes, say two? If so, how should I proceed to gild some small articles of brass?—DYER.

[61791.]—**Pumps.**—Will some correspondents kindly give me their experience? I want to draw water from the sea with two 3½in. bucket pumps. Can I draw it 1,000ft. with 28ft. lift? What should be the speed of the buckets in feet per minute? What are the best means to secure good results?—H. H.

[61792.]—**Watch Jobbing.**—I have a few cylinders and verges to turn in. Will any of your practical readers help a young one who has no one to show him, and how to try both escapements properly? If any would answer privately, I would pay for all trouble.—E. W. W.

[61793.]—**Sponge.**—Any information, the result of experience, respecting the washing, bleaching, and colouring of sponges will be acceptable to—A SPICULE.

[61794.]—**High-Pressure Steam for Heating Purposes.**—I am a printer, and have a building three stories high, containing a number of rooms. At present they are heated by hot-water pipes; but these are found insufficient, as we have no means of keeping them hot all night. We have a steam boiler on the premises, and the idea has occurred to me that the place could be much more effectually warmed if both ends of the hot-water pipes were attached to the boiler, so that the steam should circulate through them instead of the hot water, the condensed water flowing by gravity down into the boiler. In that case there would be no heat lost except by radiation from the pipes, and the wasteful mode of fizzing steam through pipes open at one end avoided. I should be much obliged if any of your practical readers would say whether this mode of heating is practical, whether the ordinary cast-iron hot-water pipes would stand the boiler pressure of 60lb. to the square inch, and whether it would be absolutely necessary that all the pipes should be above the level of the boiler?—S. P.

[61795.]—**Incandescent Light.**—I have an incandescent lamp, about 6in. in circumference, carbon film of ordinary loop form. Could anyone kindly inform me what candle-power it might be, what battery power it would require to light same, and best kind of battery to use?—BEGINNER.

[61796.]—**To Mr. S. Bottone.**—I am making a dynamo up. The size will be, Siemens H armature 6in long by 2¼. The pole-pieces are 6in. long, 2½ diam., by 3½ wide. Fields are 6in. long, 2½ by 2, upright. I want, if I can, to get six 20c.p. Will you kindly inform me how much wire I shall want on the fields and armature, and what size wire? Will the lamps want to be arranged in parallel or in series?—NEW READER.

[61797.] — **Locomotive Boilers.** — Will "Loco." enlighten me as to following? The engine Gladstone and the new North British express engines have boilers of almost exactly the same dimensions; but Gladstone has 1,492ft. of heating surface, while N.B. has only 1,102ft. On the other hand, the N.B. engine has 1sq.ft. of grate to 52ft. of h.s., while Gladstone has only 1 to 72. Which may be considered the most powerful engine?—SPECTATOR.

[61798.]—**Condenser.**—Could any of our subscribers tell me anything of which is the best kind of siphon condenser? Do they work as well as the old kind, with air-pumps, &c.? Want one for a pair of engines; h.p., 8½in. by 24in.; l.p., 14in. by 24in.; revs., 85, cut off in h.p. at ⅝ stroke; initial pressure, 60lb. I believe there are various kinds in the market, but do not know the cost.—JOINER.

[61799.]—**Boiler Front.**—Will someone tell me what will fetch the old grease off that is very rough and cracked? Also, what is best to paint it with to keep it smooth and a good gloss?—COUNTRY LAD.

[61800.]—**Setting Lever Watch in Beat.**—Will some reader tell me how to set a lever watch in beat? Is there any mark same as Geneva watches, which are so easy, or is it like many English ideas, stupid rule of thumb? I have referred to back vols.—"Seconds Practical Watchmaker." He says: "When a bar is at rest exactly over pallet hole and ruby roller pin is an exact line with that and the staff pivots." I can't see this, nor anyone else, I think. Also, how is the moon plate worked in a large clock, eight days? It is up in the arch part, with two faces painted; but this one has no connection. Inside count wheel under dial are 52 teeth doing nothing. Should something work in this? It is a modern clock cost £12, but moon does not work.—PROGRESS.

[61801.]—**Oak Cantilever.**—What must be the breadth in inches of an oak cantilever 6ft. long and 9in. deep in order to carry a load of ½ton at its extremity? The actual stress is not to exceed quarter of the breaking stress; and the breaking weight of an oak cantilever 6in. long, 1in. deep, and 1in. broad is 280lb.—BATTEN.

[61802.]—**Drilling Holes.**—I have a large number of holes to drill, ⅛in. dia., ⅛in. deep, in deal, mahogany, and brass, mostly at regular intervals of 1in. or 2in., on lathe about 3ft. long. Can any practical reader suggest a plan or a machine whereby these may be done quickly, without measuring or otherwise setting out? I have lathes, foot motors, &c.; but my difficulty lies not in the drilling, but in a quick and certain way of bringing up the stuff into required position for the next hole, and all to be equally distant apart. I have a remote remembrance of once seeing a machine doing similar work for blind lath or rails, but it was Yankee made, I believe, but cannot find one offered in any maker's list. Any information would be greatly esteemed by—LIMELIGHT.

[61803.]—**Testing Model Engine.**—What might be considered the actual gain per cent. if, when testing my model engine by means of a dynamometer, I find that, under ordinary working, a weight at end of lever attached to clip (dynamometer) of 8lb. suffices to stall the engine, whereas on connecting (throwing into gear) a peculiar arrangement (not yet patented), which I have devised, a further weight of 3lb. is required to bring engine to a

stand, pressure of steam and all else being strictly as in first (ordinary) trial, the difference appearing as $\frac{3}{8}$th? Can I consider this an actual gain equivalent to, say, 38 or 40 per cent.?—ONE PLEASANTLY PUZZLED.

[61804.]—**American Organ Question.**—Will some reader kindly say what weight of springs would be required for an American organ of eight rows in the treble, five in the bass, and one octave sub-bass, with 30 notes on the pedals? Also what size the bellows and feeders would require to be? Would the feeders do at the back, so as to be more convenient for handle? If so, what would be the most simple method of communication between pedals and feeders?—R. H. W.

[61805.]—**Lawn Tennis Tournament.**—Can any reader explain the method of drawing for tennis and billiard tournaments, so that, with an uneven number of players there shall be no "byes" after the first round? It is, I believe, called the "Bagnall-Wylde System." It is simple enough to arrange in playing "singles"; but how is it carried out for "doubles"?—A. LLOYD.

[61806.]—**G.E.R. Locos.**—Can anyone tell me (1) the number of the G.E. coupled engine exhibited in the 1862 exhibition, (2) the number of the G.E. single express engine exhibited in the Paris Exhibition, 1867, (3) principal dimensions of the new six-coupled tanks, 275 class?—EAST ANGLIAN.

[61807.]—**Organ Question.**—I am about to add to my organ in the swell a 3-rank mixture. Would any reader kindly give me instructions how to proceed? It will require to be placed at the back of the wind chest.—R. H. W.

[61808.]—**Watch Pivoting, &c.**—I have been looking through my back numbers for instructions how to use the gravers for turning pivots, &c., and have failed to find any. Would some of your horological correspondents supply me with this want, giving the shape of gravers used and the means adopted to prevent the pivots from falling off when being turned?—WORKMAN.

[61809.]—**Cyclometer.**—I propose making a cyclometer for tricycle with 48in. wheels. I thought of using two ratchet wheels, with 422 and 25 teeth respectively. Will some fellow reader inform me as to the best mode of applying same, or a better plan? A diagram showing details would be very useful, as I can find nothing on the subject in back numbers.—C. M. R.

[61810.]—**Spirit Lamp.**—Will any kind reader help me out of this difficulty? Having a small model of engine and boiler, I have tried to get a regular heat from a lamp with three burners of 3-16 brass tube, $\frac{1}{8}$ hole, $\frac{3}{8}$in. above lamp top, and $\frac{1}{2}$in. from boiler bottom, which is horizontal. The lamp is inclosed in a copper cage that carries the boiler, and which is screwed to a brass plate $\frac{1}{8}$ thick, and well perforated with air holes all round. Depth of lamp, $\frac{3}{4}$in.; length, 4in.; width, $1\frac{3}{4}$in. Now the difficulty is that the lamp, after burning a few minutes all right, gets hot, and very soon becomes a mass of flame, and, of course, soon burns itself out. I may say the burners are of the ordinary screw pattern of common oil lamps. How can I remedy this defect?—ONE IN A FIX.

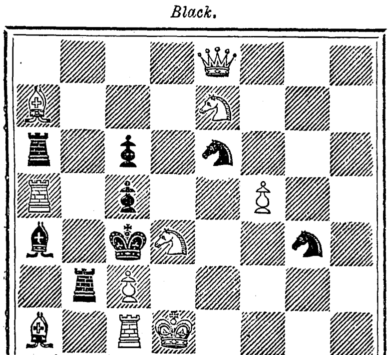
[61811.]—**Electro-Plating.**—I have been doing a little electro-plating; but have failed to plate the articles bright. I have tried bisulphide of carbon; but instead of the articles coming out bright they were a dark brown. I altered the battery power, but that made no difference. Will some kind reader of "Ours" help me out of the difficulty?—NOVICE.

CHESS.

ALL Communications for this department must be addressed to J. PIERCE, Langley House, Dorking.

PROBLEM MXXXII.—BY T. H. BILLINGTON.

Black.



White. (10 + 8

White to play and mate in two moves.

SOLUTION TO 1,030.

White.	*Black.*
1. Q-K Kt 6.	1. K takes B or (*a*).
2. Q-K B 7.	2. K-B 4.
3. Q-Q B 4 mates.

NOTICES TO CORRESPONDENTS.

CORRECT solutions to 1,030, by Black Pawn (very neat and correct), W. Hewson-Kilbee, A. Bolus, Snowdrop G. A. A. Walker, Major, H. Hosey-Davis; to 1,029, by G. A. A. Walker, Snowdrop, T. H. Billington, J. Palmer (several variations omitted); to 1,028, by A Beginner and J. Palmer.

A BEGINNER.—1,030 cannot be done as you propose.

TERMS OF SUBSCRIPTION.

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom. For the United States, 13s., or 3 dol. 25c. gold; to France or Belgium, 13s., or 16f. 50c.; to India (via Brindisi), 15s. 2d.; to New Zealand, the Cape, the West Indies, Canada, Nova Scotia, Natal, or any of the Australian Colonies, 13s.

The remittance should be made by Post-office Order. Back numbers cannot be sent out of the United Kingdom by the ordinary newspaper post, but must be remitted for at the rate of 4d. each to cover extra postage.

Messrs. JAMES W. QUEEN and Co., of 924, Chestnut-street, Philadelphia, are authorised to receive subscriptions for the United States for the ENGLISH MECHANIC, at the rate of 3 dols. 25c. gold, or Thirteen Shillings per annum, post free. The copies will be forwarded direct by mail from the publishing office in London. All subscriptions will commence with the number first issued after the receipt of the subscription. If back numbers are required to complete volumes, they must be paid for at the rate of 4d. each copy, to cover extra postage.

Vols. IV., VII., XXVI., XXVIII., XXX., XXXII., XXXIII. XXXIV., XXXV., XXXVI., XXXVII., XXXVIII., XXXIX., XL., XLI., XLII., and XLIII., bound in cloth, 7s. each. Post free, 7s. 9d.

All the other bound volumes are out of print. Subscribers would do well to order volumes as soon as possible after the conclusion of each half-yearly volume in February and August, as only a limited number are bound up, and these soon run out of print. Most of our back numbers can be had singly, price 2d. each, through any bookseller or newsagent, or $2\frac{1}{2}$d. each, post free from the office (except index numbers, which are 3d. each, or post free, $3\frac{1}{2}$d.).

Indexes for Vols. I., VI., VII., VIII., and IX., 2d. each. Post free $2\frac{1}{2}$d. each. Indexes to Vol. XL., and to subsequent vols., 3d. each, or post free, $3\frac{1}{2}$d. Cases for binding, 1s. 6d. each.

NOTICE TO SUBSCRIBERS.

Subscribers receiving their copies direct from the office are requested to observe that the last number of the term for which their subscription is paid will be forwarded to them in a PINK Wrapper, as an intimation that a fresh remittance is necessary, if it is desired to continue the Subscription.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 332, *Strand, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustrations on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Letters or queries asking for addresses of manufacturers or correspondents, or where tools or other articles can be purchased, or replies giving such information, cannot be inserted except as advertisements. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded, and the names of correspondents are not given to inquirers.

***** Attention is especially drawn to hint No. 4. The space devoted to letters, queries, and replies is meant for the general good, and it is not fair to occupy it with questions such as are indicated above, which are only of individual interest, and which, if not advertisements in themselves, lead to replies which are. The "Sixpenny Sale Column" offers a cheap means of obtaining such information, and we trust our readers will avail themselves of it.**

The following are the initials, &c., of letters to hand up to Wednesday evening, Feb. 23, and unacknowledged elsewhere:—

J. W. QUEEN AND CO.—S. R. Bottone.—Amateur.—W. H., Newport, Mon.—H. A. C.—T. R. Glanfield.—N. M. M.—Beginner.—A Country Parson.—G. E.—A. H. J.—G.—Moyhitt.—F. C. S.—Violinist.—G. and S.W. Ry. Fitter.—J. R.—E. P. M.—H. J. Hardy.—Jigger.—Valve Rod.—Inquiry.—A. J. L.—Apollo Belvedere.

O. P. Q. (This volume ends with the present number. It commenced with the number for Sept. 3 last. The papers on "The Amateur Workshop" commenced in No. 1035.)—J. FAIRFAX. (Do not understand you. The crystals of Glauber's salt, sulphate of soda, rapidly effloresce when exposed to the atmosphere, especially if the air is dry and warm. How many tons a day would you want to convert into powder?)—COMPOUND. (See the "Brakes Return," or refer to indices of back volumes. Perhaps the table in No. 1105, p. 282, will give you sufficient information.)—TOM. (There are many in back volumes, and one in last week; but in all the important ingredient is elbow-grease. Bath-brick, whiting, jewellers' chalk, rouge, &c., are all good polishers when properly applied.)—EBBO. (If former query was received it was no doubt answered in this column, for such matter has been dealt with many times. See p. 38, No. 1094; p. 430, No. 1087; or Nos. 995, 999, 1039, 1041. The four numbers last mentioned contain full explanations of various slide-valve diagrams.)—TESTER. (You do not seem to be aware that the mercurial column is the oldest form of barometer. Presumably you want information about old-fashioned weather-guides, like those with the man and woman to come outside the door in rainy and fine weather respectively; but you say weather-glasses, and we must refer you to indices and to works on the subject, for there are many designs, generally of little, if any, use.)—G. M. S. (The "Guide to the Whitworth Scholarships" can be obtained from the Secretary of the Science and Art Department, South Kensington, or of any bookseller by order. The price is sixpence. There is a useful book giving hints to candidates published in your city by Mr. Heywood. 2. The water cannot be forced higher than the level of the cistern. The supply flows down from the bottom of the cistern, and the hot-water is discharged at the top—that is, what is not drawn off en route. A sketch in No. 1029.)—LADY GARDENER AND HOUSEKEEPER. (Your questions were answered on p. 532.)—S. M. (Consult the catalogue issued by Mr. Fletcher, Warrington, and you will probably find something suitable. For Turkish baths at home, see Nos. 900, 901, 902.)—J. S. (You have only to procure Pitman's works, and practise diligently. Pitman's is in Paternoster-row, and the necessary manuals cost only a couple of shillings or so. Learn the signs thoroughly, and then practise as hard as you can by taking down the words of a lecture, or of the reader of a paper which will be published. Then you can compare your work and see how you have done it.)—ARTHUR GAPP. (The best way is to obtain employment in an engineering shop and enter as a student at the Finsbury Technical College.)—MARINE. (1. Premiums are as a rule required in good engineering shops, though they are low when the apprentice enters as a worker. 2. Depends entirely on arrangements. 3. There are plenty of shops near London, the one you mention being amongst the best, especially for marine work. 4. Reed's "Engineer's Handbook," published by T. Reed and Co., Sunderland.)—A SCIENCE STUDENT. (All information of the kind can be obtained by consulting the "Calendars" of the respective universities. The degrees B.Sc., D.Sc., are granted by London, Edinburgh, and Glasgow.)—CARINO. (See numerous articles on the subject in back volumes under heading of "Lantern Transparencies." See, for instance, No. 1091, p. 510, and a letter in No. 1093, p. 13.)—E. R. D. (They are embossed in the usual way, using a yellow ink or plain gold size or printer's varnish. The powder (imitation gold or Bessemer's gold) is dusted on, and the surplus removed with cotton wool or a hare's foot.)—T. LAIDLER. (Machines for making matches illustrated in Nos. 785, 786. We do not know the names of the makers.)—DELTA. (You do not seem to be aware that exactly what you require was given not long ago. There are three different designs of footblowers in No. 1111, p. 423; a mineralogist's arrangement in No. 1075, p. 185; a handblower in No. 975; and a variety of other devices in back volumes. See also the catalogue issued by Mr. Fletcher, Warrington.)—M. KEOGH. (Mixing with a solution of alum retards the setting; but you cannot make plaster of Paris into "putty" and retain its special properties.)—RAMESES. (You could have a reflecting lantern, or you could enlarge them by photography. To exhibit such illustrations in lectures, the only really satisfactory way is to make transparencies and show them by means of the lantern. You will find full details in recent volumes.)—YOUNG AMATEUR. (Instructions of the kind are not to be given in a few lines. Before attempting to plate with gold, you should procure and read some such book as Watts's "Electro.-Metallurgy," Crosby Lockwood and Co., price 3s., in which you will find directions for making several solutions.)—JAS. WADE. (We do not know of any "practical" works on the subject; but there is a good deal of information on details in back volumes. Perhaps the treatises published by E. and F. N. Spon, 125, Strand, may supply your wants. One is Hedge's "Useful Information on Practical Electric Lighting," 3s. 6d.)—TRAVELLER. (No work giving such information in full. The best is, perhaps, Vernon Harcourt's "Treatise on Rivers and Canals," Oxford Press, £1 1s.; but that gives only examples.)—ALARMED. (Consult the lists issued by publishers. Such queries only afford an opportunity for the gratuitous advertising of books, and are of little, if any, interest to anyone but the questioner.)—W. H. DEVONPORT. (The only way to obtain situations in the engine-room of steam vessels as supernumerary engineer is to apply to chief engineers on board, or to managing owners. As you have had three years' experience in the engine factory, you will have to serve only one year at sea in the engine-room before sitting for the certificate. If, as we understand, you could make yourself very handy and useful in doing repairs, you ought to have little difficulty in getting a berth, and if you determine to go in for the certificate you cannot do better than procure Reed's "Engineers' Handbook" (T. Reed and Co., Sunderland), and study that thoroughly during the interval.)—JAMES SINCLAIR. (Why not give the information through our columns for the benefit of all interested?)—G. M. S. (Is there not a library in your great city where you could see various books on the subject, and choose for yourself? Maxton's "Engineering Drawing," Crosby Lockwood and Co. may perhaps suit you.)—BOILER-MAKER. ("The, Theoretical and Practical Boiler-Maker," by S. Nicholls, published by the author at Blackpool, we think; but procurable through Mr. Calvert, Great Jackson-street, Manchester, whose catalogue will give you the titles of other works which may be suitable.)—AMITURE. (It is not easy to find the "query" in your rambling statement. You cannot expect much of a spark with only 3oz. of No. 40, and the primary should be preferably covered. Directions for making coils have been given over and over again. If querists will not follow directions, they must expect to fail. See No. 1117, p. 564, and the indices of back volumes. Or look on pages 18, 138, 176. 225, 309, 310, 390, 398, 439, 550, of the present volume for a good deal of information. 2. No cheap books on that special subject. Sprague's "Electricity" is published by E. and F. N. Spon, 125, Strand, W.C., price 15s. It is in the second and enlarged edition, and is published in one form only.)—JOE. (Generally done by means of a scraping tool, with light touches.)—TINKER. (First query against the rules. See Hints No. 4.)—J. H. (No doubt if you advertised for working drawings some one would offer to supply them; but if you can refer to Clegg's or King's "Treatise on the Manufacture of Gas," you will be able to work out the required drawings from the illustrations.)—V. J. B. (No; the standard gauge, however, is very near the old B.W.G. It has been given several times, most recently in No. 1101, p. 199, and the B.W.G. can be found in most of the pocketbooks.)—J. H. B. (There are many recipes for silvering glass in back numbers; but if it is "ordinary looking-glass" that you require it is much cheaper to purchase pieces from the makers. See No. 1072, p. 125, and the indices generally.)—A REGULAR SUBSCRIBER. (See pp. 353, 373, this volume, or p. 456, No. 1088, for polishing and removing stains from black marble.)—I. KONER. (The only way is to become an apprentice to an electrical engineer, or to obtain work in a shop where electrical apparatus is made.)—SR. ARTURO HEEREN. (Prof. Fuller's spiral slide-rule is manufactured by W. F. Stanley, Railway Approach, London Bridge, S.E.)—A CLOCKMAKER'S APPRENTICE. (Surely you are acquainted with Britten's "Watch and Clockmakers' Handbook," in which you will find the rule for calculating length of pendulum.)—VOLTMETER. (See the indices of back volumes. It would require several columns to answer your questions fully. The first question seems to be contradictory, and

the others have been answered or are unanswerable, except at considerable length.)—R. W. (What sort of black do you want? Will blacklead do, or must it be a stain? It cannot be done by merely dipping in acid. See No. 944, p. 168, No. 1086, p. 401, and the indices generally.)—ARTHUR. (A coil constructed on what you call the "latest style" was illustrated and described so far back as p. 472, Vol. XI., and in almost every volume since there have been directions more or less complete for making coils. You will find a good deal about section-wound coils in Vols. XLII. and XLIII. No. 885, if you can get it, will give you some useful information. See answer to "Amiture" above.)—HOBSON JOBSON. (There is a small hole in the brass cap, or the upper end is covered with bladder. Not worth making, but you will find the proportions in the "Answers" for Nov. 12 last, p. 250, this volume. 2. Shenstone's "Glass-Blowing," published by Rivingtons; Glazebrook and Shaw's "Practical Physics," may answer for the other, or Weinhold's "Experimental Physics," both published by Longmans.)—T. RICHARDSON. (Shenstone's "Glass Blowing" is published by Rivingtons, and was reviewed at some length on p. 25 of this volume. 2. Prof. S. P. Thompson's "Electricity" is published by Macmillans, and was reviewed on p. 45, Vol. XXXV.)—MEDICAL. (We are not aware that there is such a method, nor that there is a work dealing with the subject. Consult a surgeon, and take his advice about the tumour. Electricity is very useful in his hands occasionally; but amateur surgeons had better leave it alone.)—F. J. LORD, MECHANIC, and other inquirers about Marine Engineers and their Certificates. (Candidates for the certificates of the Board of Trade may obtain all requisite information at any mercantile marine office. They must have served an apprenticeship of at least three years in the making and repairing of engines, or have been employed as journeymen mechanics for that time in similar work, and at least one year in the engine room "on the watch." Or where there is no practical workshop experience, candidates must have served at least four years in the engine room "on the watch." See Reed's "Engineer's Handbook," published by T. Reed and Co., Sunderland.)—J. A. E. MITCHELL. (Send sketch and drawing, and we will see.)

CHARGES FOR ADVERTISING.

	s.	d.
Thirty Words	2	6
Every additional eight words	0	6

Front Page Advertisements Five Shillings for the first 40 words, afterwards 9d. per line. Paragraph advertisements One Shilling per line. No front page or paragraph advertisement inserted for less than Five Shillings. Reduced terms for series of more than 6 insertions may be ascertained on application to the Publisher.

ADVERTISEMENTS in EXCHANGE COLUMN—for

Twenty-four words	0	3
For every succeeding Eight Words	0	3

ADVERTISEMENTS in the SIXPENNY SALE COLUMN.

	s.	d.
Sixteen words	0	6
For every succeeding Eight words	0	6

*** It must be borne in mind that no Displayed advertisements can appear in the "Sixpenny Sale Column." All advertisements must be prepaid; no reduction is made on repeated insertions and in cases where the amount sent exceeds One Shilling, the Publisher would be grateful if a P.O.O. could be sent, and not stamps. Stamps, however (preferably halfpenny stamps), may be sent where it is inconvenient to obtain P.O.O.'s.

The address is included as part of the advertisement, and charged for.

Advertisements *must* reach the office by 1 p.m. on Wednesday, to insure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

The charge for Exchange Notices is 3d. for the first 24 words, and 3d. for every succeeding 8 words.
